Message from the Editor in Chief

JOURNAL OF THE LATIN-AMERICAN ASSOCIATION OF QUALITY CONTROL, PATHOLOGY AND RECOVERY OF CONSTRUCTION

http://www.revistaalconpat.org

With great satisfaction, we present the first issue of the ninth year of the ALCONPAT journal.

The aim of the journal is to publish case studies within the scope of the Association, namely quality control, pathology and recovery of constructions, including basic and applied research, reviews and documentary research.

The V9 N1 issue begins with a work where Nicolle Christine Sotsek and colleagues provide, through a systematic review of the literature and focused on the quality control of buildings, a consistent database to present the most used criteria by the Building Performance Evaluation (BPE). It was possible to define 9 dimensions of analysis that are presented and discussed in this document.

In the second work, Cristiano Corrêa et. al. present the computational simulation of a fire previously carried out as an experiment in a room that reproduced a single-family residence room, typically burnt down in the city of Recife (Pernambuco, Brazil). The objective of the article is to compare the results of the development of the temperatures of the gases obtained through computer simulation with the Fire Dynamics Simulator software (FDS) through the measurements obtained in the experiment. It was verified that the results obtained through the model developed in the FDS were coherent with those obtained experimentally.

In the third article, Mauricio de Pina Ferreira et. al. evaluate the influence of anchoring on the flexural strength of beams reinforced with Carbon Fiber Reinforced Polymer (PRFC) blankets. The parameters affecting the performance and strength of the beams are evaluated, and the sizing criteria of FIB Bulletin 14 (2001) and ACI 440-2R (2008) are discussed. It was observed that, even with auxiliary devices in the anchoring of the PRFC, there is the possibility of premature failures, and that both recommendations lead to safe, but overly conservative estimates in cases where the anchoring of the PRFC blanket is carried out properly.

In the fourth article, by Yagho de Souza Simões and Carol Ferreira Rezende Santos, we compare two techniques of structural reinforcement, carbon fiber and metal foil, used for the recovery of reinforced concrete structures degraded by fire. A deterioration of a beam in a fire situation is simulated from a thermal numerical modeling and, next, the reinforcements are calculated. It is concluded that carbon fiber has greater advantages regarding the reinforcement of beams.

The fifth work in this issue is written by Ricardo José Carvalho Silva and colleagues, who analyze the efficiency of reinforcement in reinforced concrete beams by adding steel bars and epoxy adhesive. The tests showed that the clamps reduced the strength of the beams, compared to those that did not. The reinforced beams without clamps obtained better results, but the most important limiting factor was the adhesion between the epoxy and the beam. The use of clamps to try to solve the problem of adherence gave originality to this investigation.

In the sixth work, Marcela Tavares de Araujo Silva and colleagues evaluate an ultrasound test to estimate the depth of cracks in the concrete, using a mathematical model of the literature, in addition to checking the depth with better results. The results show that the test is sensitive to detect the presence of cracks in the concrete. The mathematical model used allowed to estimate the most depths of fissures; but the results are scattered and with a high margin of error for the depths of 5 cm and 15 cm, since for 10 cm better results were observed.

The seventh work in this issue is written by Renato Guilherme Pereira and colleagues, who present an experimental program to determine the residual strength of bi-supported reinforced concrete beams subjected to pure bending after fires. The beams presented, up to 120 minutes of exposure to fire, a good performance after the fire, not showing a significant reduction in their residual strength, and the numerical model was accurate in forecasting the temperatures and the residual rupture load when the experimental results were compared.

The article that closes this edition is by Erick Maldonado et. al. they present the results of concrete manufactured with supersulfated cements (SSC) volcanic material bases. After 180 days, the concrete with a cementitious compound of 5% An-10% CP-10% CaO-75% PM exposed to the CaSO4 solution reached a compressive strength of 46 MPa and 44 MPa in dry conditions. laboratory. The microstructure was analyzed by scanning electron microscopy, energy dispersion spectroscopy and XRD, showed that the main hydration products are C-S-H and ettringite.

We are confident that the articles in this issue will be an important reference for those readers involved with issues of modeling applications and service life, as well as inspections with modern and / or improved methodologies. We thank the authors participating in this issue for their willingness and effort to present quality articles and meet the established times.

On behalf of the Editorial Board

REVIEW

APPLIED RESEARCH

A systematic review of Building Performance Evaluation criteria (BPE)

N. Christine Sotsek1*, D. Sanchez Leitner1, A. P. Lacerda Santos1

*Contact author: nicollesotsek@yahoo.com.br

DOI: http://dx.doi.org/10.21041/ra.v9i1.260

ABSTRACT

The objective of this article is to provide, through a systematic review of the literature, focused on the quality control of buildings, a database to present the Building Performance Evaluation (BPE) most used criteria. Through this review, 782 articles were identified, of which 15 were selected considering the subject's adherence to the research and publication period. It was discussed the main information about the articles, their authors and journals. The performance criteria compiled by the analyzed articles used as basis: literature, questionnaires and interviews with users and professionals of the area, consultation with specialists in the segment and technical visits to buildings. With these identified criteria, it was possible to define 9 dimensions of analysis that are presented and discussed in this document.

Keywords: performance; evaluation; criteria; construction; systematic review.

A systematic review of Building Performance Evaluation criterias (BPE)

1. INTRODUCTION

A building is built with the aim of providing the human being with a pleasant and comfortable working environment, and protected against climatic inclement weather (Khalil et al., 2008). However, a building is the result of a project and planning built and managed based on specific standards established by governments, professionals and specialists who must meet not only the current technical requirements of each country, but also the expectations and aspirations established by the users (Ibem et al., 2013).

Based on this discussion, it is important to realize the importance of this research by considering that high population indexes is essential for more buildings to be built, but at the same time continue to meet the requirements established by the standards and by the final owners.

The performance of a building can be defined as its capacity to operate at maximum efficiency, fulfilling its function throughout its life cycle (Khalil et al 2016). To provide this maximum operation and to improve its efficiency, regular and continuous evaluation of building performance, called building performance evaluation (BPE), is essential. The BPE is a process of systematic comparison of the real performance of a building, that is, it relates the objectives of the client with the criteria of performance established by the specialists in order to measure the degree of satisfaction and performance of a building for those users (Preiser, 1994). This process aims to...
improve the quality of management, design and construction by providing a more sustainable construction (Ibem et al., 2013); provide basic information on users’ needs, preferences and satisfaction (Vischer, 2008) and provide feedback on the causes and effects of environmental issues related to buildings, thus informing the long-term planning and management of the life cycle of buildings (Meir et al., 2009). To do so, the BPE serves as a tool that adds value, assisting managers in decision making at strategic and operational levels during construction of a building (Khalil et al., 2008). However, for the application of the BPE it is necessary to define the evaluation criteria that can help in the process of measuring the performance of a building. According to Teicholz (2003), one can not improve what can not be measured. Measuring the performance of a building, according to Koleoso et al. (2013), is the safest way to improve the economic, physical and functional development of a building, ensuring that its objectives are met. Based on this assumption, this article aims to present a brief overview, through a systematic review of the literature, of the main academic studies that have studied and established performance criteria for the evaluation of buildings in order to assist in the expansion of this area of research focused on the control of quality of buildings.

2. MATERIALS AND METHODS:

This research adopted a systematic review approach proposed by Kitchenham et al. (2009) and followed three main steps (Figure 1): (1) Review planning; (2) Conduct of review; (3) Dissemination and reporting.

![Figure 1. Process of applying the systematic review. Adapted from Kitchenham et al., (2009)](image)

The first phase of the research proposes to align the research theme and elaborate the collection protocol. The central theme established for research was to identify the criteria established in the literature for evaluating the performance of buildings. Based in this thematic, the collection protocol was elaborated, selecting 3 international databases: Web of Science, Scopus and Science Direct, and a Brazilian database, the CAPES. In each database, terms related with performance evaluation in construction had been tested. In the search string it had used the logical boolean operators AND, OR and the quotations marks for bigger precision of the research, until two terms were defined: “building performance evaluation” and “building performance criteria”.

In the second phase of the research, the articles were selected based on the scope of the theme, that is, if the article had as its essence the definition of criteria for performance evaluation of buildings; the period of publication (2010-2017) and the search for articles of Journals, discarding articles of congresses. After this selection, a dynamic reading of the articles was performed and in this step, it was possible to obtain more articles by referential means cited by the authors. This process created a looping and stopped only when no articles were applied to the topic. The identified articles were organized in an Excel spreadsheet.

This technique of searching for new articles from those already selected is known as Snowball Sampling (ABN) and was reported by (Biernacki and Waldorf, 1981). Finally, in the third phase of the research it was possible to elaborate the articles bibliometry and content revision. In the first
one, we tried to measure the main aspects related to the articles, the authors and the magazines. The mechanism used to identify the citations of articles and the scores of journals was the platforms “Scopus- Search for an author profile”, “Scopus- Journal Metrics” and “Scimago Journal & Country Rank”. Based on all the keywords identified in the articles, the word cloud was created using the online software "Word it out". The objective of this stage was to understand the panorama of research in the world, identifying the main authors and journals. In the second stage, the proposal was to compile the information present in the articles, organizing them into four groups: (1) methods used to elaborate the performance criteria; (2) conducting the questionnaires used; (3) organization of the criteria identified in 9 dimensions and (4) preparation of a table compiling all the criteria identified in the established dimensions.

3. RESULTS AND DISCUSSION

Through the systematic review of the literature, the two selected keywords «building performance evaluation» and «building performance criteria» were inserted into the four selected databases: Web of Science, Scopus, Science Direct and CAPES. In the first round, 782 articles were identified. With this sample we selected articles from 2010-2017, peer-reviewed Journal and Journal articles, reducing the sample to 424. With these, a dynamic reading was performed, which is a reading of the main topics such as abstract, method and result, and it were chosen the articles that presented in their conception the elaboration of a BPE method and selection of criteria. Then, the technique of Snowball Sampling was applied until the end of the identification of articles adhering to the theme. Table 1 presents in detail the procedure performed up to the selected number of 15 articles.

*With the 15 articles selected, it was possible to perform bibliometric and content revision.

3.1 Bibliometric

In Table 2 it is possible to identify the authors name, the database where the article was identified, the name of the journals, their "DOI" registry and the country of origin. The journals that published the most works (from 2010 to July 2017) identifying criteria for performance evaluation in buildings were: United Kingdom (60%), followed by the Netherlands (13.33%), China, USA, Egypt and Lithuania (6.66%). It is noticed that more than 85% of the publishing magazines are from Nordic countries.

However, it can be seen from Figure 2 that most research and research authors are concentrated in Western countries. Malaysia is the country with the largest number of researchers.
Figure 2. Information about the country of origin of the research and the authors.

Through the "Scopus- Search for an author profile" platform, it was possible to verify the most cited articles and the co-quotations made between them (Table 3). The article by (Steinke et al., 2016) was the most cited in the literature, followed by the article by (Mohit and Naydaah, 2011). Table 3 shows how many times the articles were cited in the literature in general, and where there were cases of citations between them.

A systematic review of Building Performance Evaluation criterias (BPE)

N. Christine Sotsek, D. Sanchez Leitner, A. P. Lacerda Santos
The “Scopus-Journal Metrics” and “Scimago Journal & Country Rank” platforms made possible to know more about the magazines identified. The information presented in Table 4 refers to the number of publications for the years 2015-2016, the score of each journal according to its area of registration, its rank and its impact on the platform Scopus and Scimago.

A systematic review of Building Performance Evaluation criterias (BPE)

N. Christine Sotsek, D. Sanchez Leitner, A. P. Lacerda Santos
With the keywords identified in the 15 articles selected, it was possible to use the "Word it out" software to create the word cloud. The three words most highlighted by the articles were as follows: Performance, Building and Evaluation (Figure 3). This cloud of words gives an overview of what has been studied within these articles in relation to the evaluation of buildings, subjects such as: aid in the decision making of enterprises; improvement of the processes and physical conditions of buildings. The researched places: corporate sector (offices); education (schools and universities). What is being used as an instrument, such as questionnaires; post-occupation analysis, among others.

![Figure 3. Keyword cloud](image)

3.2 Content Review

The 15 works identified in the literature used several methods to elaborate the criteria for evaluating the performance of buildings. By consulting these articles, it was noticed that the review of the literature was the method used in all articles, that is, the authors sought to first explore the criteria already listed and identified in the literature and then spent, for the most part, exploring the criteria in practice. The criteria were tested, evaluated and validated through questionnaires (67%) made with users and / or construction professionals, such as engineers and architects. In 30% of the questionnaires applied, specialists of the area were consulted firstly, and then the users. In 20% of the used questionnaires only the specialists were consulted. In the questionnaires applied, the Likert scale was the instrument used in 50% of these.

The technical visit consisting of a visual analysis of the buildings and consultation of documents, such as design and technical data sheets, was the method used in 33% of the articles. It was not used in isolation, but always in conjunction with other methods. The interview was used in 27% of the articles, being carried out with users and / or professionals of the area. The AHP method (7%) was explored on a smaller scale, applied in the link with expert consultation. The full picture of the methods employed can be seen in Table 5.

The questionnaire was the second method most used by the authors to identify the criteria needed to evaluate a construction. Of these, 80% were applied, and 20% were not applied, that is, in the case of the 20%, the authors present the questionnaire as a reference and as an instrument to test the criteria but did not actually use it. In the questionnaires applied, in short, about 3,196 questionnaires were sent. Only the work of (Nik-Mat et al., 2011) sent 1,230 questionnaires. The response rate varied from 20.4% to 100% in the applied works. To select the respondents to the questionnaires, the most used criteria was the working time in the area, in the case of the specialists, and for the users, the dwelling time of the dwellings. The works organized the criteria into dimensions that were validated. In some cases, the criteria were reorganized and then validated by the authors (Table 6).

A systematic review of Building Performance Evaluation criterias (BPE)

N. Christine Sotsek, D. Sanchez Leitner, A. P. Lacerda Santos
In full, each article provides a range of criteria that should be analyzed to evaluate the performance of a building. In some cases, the articles created dimensions to organize their criteria, in others, the articles presented the criteria without presenting a specific group. In this way, the authors of this paper organized the criteria identified in the articles in 9 dimensions established from the reading of the works (Table 7).

</table>
It can be seen from Table 7 that 20% of the articles are concerned with creating criteria that evaluate constructions in general. However, the other 80% show that it is important to establish specific criteria for each type of construction, in the case of housing, education, health and commerce. The nine dimensions elaborated involve the analysis of aspects related to the functional condition of a building, such as: air condition, ambient (acoustic and thermal comfort), noise, fire protection, lighting, among others; the technical condition involves the structure of the building, plumbing and electrical services, for example. The environment dimension refers to the spaces (of the rooms) and location of the enterprise; the financial dimension involves expenses related to building (maintenance, light, water). The environmental dimension refers to the spending index on light, water and garbage collection; the image dimension involves the aesthetics and appearance of the buildings.

The dimension "relationship between neighborhood" presents the contact of the residents with the surroundings. The "processes" dimension involves the control and management of the services provided within an enterprise and finally the leadership dimension refers to the instructions established to the owners and employees in the construction occupation. The most used dimensions during the constructive evaluation refer to Functional (93%) and Technical (93%), followed by Environment (88%).

The evaluation criteria identified in the 15 articles studied and organized in 9 dimensions are presented below:

- **Gopikrishnan and Topkar (2017):** Thermal comfort; ventilation; visual comfort (natural lighting); fire safety, lightning, accidents in general; acoustic comfort; water control; control of air quality; control of drinking water and electricity services; building maintenance (fissures, leaks, infiltration, humidity, sewage); control of basic sanitation; control of internal and external finishes to the building; evaluation of spaces such as size of internal and external areas, accessibility to the connectivity of the building (networks), the surrounding roads, stairs and elevators internal to the building. Control of garbage collection and maintenance of building aesthetics.

- **Ibem et al (2013):** Visual control; thermal and acoustic; control of air quality; fire safety, insects, dangerous animals, moisture; building maintenance; control of electrical and sanitary services; evaluation of the internal spaces, the design of the building and its location (accessibility for residents); control of the costs with the building; control of the aesthetic appearance of the construction and materials used in construction.

- **Khalil et al (2016):** fire safety; thermal comfort; visual comfort (artificial and natural lighting); waste control; ventilation; acoustic comfort; assessment of structural stability; electrical and sanitary services; control of finishing materials; building cleaning control; evaluation of the size of the spaces and the circulation and evaluation of the signage of the environments in the building.

- **Khan and Kotharkar (2012):** fire safety; visual comfort; assessment of structural stability; control of sanitation services; evaluation of internal space sizes; evaluation of the flexibility of the internal environments and control of the aesthetics of the building.

- **Steinke et al (2010):** evaluation of how the building contributes to the quality of life of residents / employees; level of innovation and practicality of the building; level of expenditure (energy and water) and level of satisfaction of the residents / employees.

- **Nazeer e Silva (2016):** visual control (natural lighting); thermal comfort; control of safety equipment, internal hygiene of buildings; olfactory control of environments; evaluation of internal and external signaling of environments; acoustic control; ventilation; internal maintenance of the building; structural control; durability of materials; assessment of accessibility and flexibility of spaces by residents; accessibility that the building possesses to those with physical disabilities; evaluation of signage of the environments in the building; evaluation of costs related to building (financing and maintenance of the
building); waste control; assessment of existing resources to assist in waste management; control of building aesthetics; existing processes check the residents' knowledge regarding maintenance, use of resources; waste management; fire safety, among others and level of training that the users obtained to do proper maintenance of the building.

- Talib et al (2013): evaluation of how the construction contributes to the quality of life of residents / employees; control of the structural and electrical quality of the building; accessibility of spaces and evaluation of the quality of building design.
- Støre-Valen and Lohne (2016): Evaluation of the functionality, usability, flexibility of the building and the sustainable resources existing in the building.
- Mohit and Azim (2012): environment ventilation; accessibility of electricity services, such as quantity of power plugs; control of electrical and sanitation services; evaluation of the size of spaces; location of the building (accessibility to residents); parking leisure areas; control of waste collection and neighbor relationship (level of security, involvement with the neighborhood).
- Nik-Mat et al (2011): air quality control; visual control; security level of the building; control of cleaning, maintenance of internal and external building and accessibility of internal and external spaces (parking).
- Hashim et al (2012): thermal comfort, acoustic, visual, ventilation; comfort of the environment; control of building maintenance, materials used in construction; cleaning; evaluation of the accessibility of the building for residents in terms of location, room space, parking and accessibility for the physically handicapped; evaluation of the costs related to building (maintenance, energy, waste, among others) and evaluation of the aesthetics of construction.
- Lavy et al (2010): evaluation of how the building brings a sense of comfort to the residents, considering level of safety and hygiene; thermal comfort, acoustic, visual (natural lighting), air quality; building maintenance; control of sanitary and electrical services; evaluation of the accessibility of the building for residents in terms of location, room space, parking and accessibility for the physically handicapped; evaluation of the costs of maintenance of buildings, energy, water); control of waste collection; control of the aesthetics of the building (finishing) and relation of involvement of the neighborhood with the building.
- Mohit and Nazyddah (2011): acoustic comfort; ventilation; accessibility of electricity services, such as quantity of power plug; fire safety; evaluation of the rooms (physical structure); assessment of accessibility of the building, such as presence of suitable corridors, stairs, elevators, parking; building access to community conveniences and control of waste collection.
- Lai and Man (2017): thermal comfort; visual; acoustic; air quality; satisfaction of users and / or professionals; security percentage of the building; building efficiency in relation to maintenance time; evaluation of preventive and corrective maintenance; building costs (maintenance, staffing, site insurance, among others) and control of energy consumption by building users.
- Elyna Myeda et al (2011): Visual comfort (lighting); air quality; building safety; control of the finishes (internal and external) of the building; general maintenance of the building; control of cleaning and electrical and sanitary services; evaluation of the accessibility of the building to the residents, such as stairs, elevators, spaces signaling, parking and control / maintenance of the landscaping and design of the building.

4. CONCLUSIONS

In this paper, a set of criteria established by authors for building performance evaluation (BPE) is presented in detail. The systematic review approach, together with the Snowball Sampling technique resulted in the identification of 15 articles. Both bibliometric and the content of these
articles were investigated. The United Kingdom is the country responsible for publishing the largest number of papers in this area, although most of the research conducted and the authors are from the eastern countries like Malaysia and India. The citations of the articles and the punctuation of the respective journals were also verified, realizing that there is a reasonable number of co-citations among the studied subjects.

In addition to the literature search by the BPE criteria, the articles also used practical methods, such as questionnaires, expert consultation, interviews and technical visits to buildings. The articles show a concern in the elaboration of specific criteria for each type of construction instead of establishing criteria for buildings in general. The criteria identified were grouped into 9 dimensions: functional, technical, environment, financial, environmental, physical image / appearance, neighborhood relation, process and leadership. The criteria most used to evaluate a building were the criteria listed in the functional and technical dimensions, such as: thermal comfort, visual (lighting), acoustic, fire safety, air quality, maintenance and cleaning of facilities (sanitary and electrical) of the building.

The authors hope that this research will help those who study the performance evaluation of constructions in order to facilitate the identification and more adequate selection of the studied criteria.

5. ACKNOWLEDGEMENTS

This research was supported by the Post-Graduate Program in Engineering and Civil Construction (PPGECC) at the Federal University of Paraná (UFPR).

ABSTRACT
This article presents a computer-made simulation of a fire that had already been done through an experiment in a room that reproduced a bedroom of a one-family residence, which is a typical case of burned construction in the city of Recife (Pernambuco - Brazil). The experimental test of this fire has been presented by Corrêa et al. (2017), and the study presented in this article has as objective to compare the results on the development of the temperature of gases, got from the computer-made simulation with the software Fire Dynamics Simulator (FDS) with the values got by the experiment. We have found out that the temperature obtained through the model developed by the FDS were coherent with the ones obtained by experiment.

Keywords: Buildings' Fire Prevention (BFP); fire in rooms; fire in residences; computer-made fire simulation; fire dynamics simulator.

Simulação numérica e experimento de incêndio em dormitório residencial

RESUMO
Este artigo apresenta a simulação computacional de um incêndio realizado experimentalmente em um cômodo que reproduziu um dormitório de residência unifamiliar tipicamente incendiada na cidade de Recife (Pernambuco – Brasil). O ensaio experimental deste incêndio é apresentado por Corrêa et al. (2017), e o estudo discutido neste artigo tem por objetivo comparar os resultados de desenvolvimento de temperaturas dos gases obtidos através da simulação computacional com o software Fire Dynamics Simulator (FDS) com as aferições obtidas experimentalmente. Verificou-se que os resultados de temperaturas obtidos através do modelo desenvolvido no FDS foram coerentes com os obtidos experimentalmente.

Simulación numérica y experimento de incendio en dormitorio residencial

RESUMEN
Este artículo presenta la simulación computacional de un incendio previamente realizado como un experimento en una habitación que reproducía un cuarto de residencia unifamiliar, y ejemplo típico de construcción incendiada en la ciudad de Recife (Pernambuco - Brasil). El ensayo experimental de este incendio es presentado por Corrêa et al. (2017), y el estudio discutido en este artículo tiene por objetivo comparar los resultados del desarrollo de las temperaturas de los gases obtenidos a través de la simulación computacional con el software Fire Dynamics Simulator (FDS) con las medidas obtenidas en el experimento. Se ha verificado que los resultados obtenidos a través del modelo desarrollado en el FDS han sido coherentes con los obtenidos experimentalmente.

Palabras-clave: Seguridad Contra Incendios en Edificaciones (SCIE); Incendios en habitaciones; Incendios en residencias; Simulación computacional de incendios; Fire Dynamics Simulator.

1. INTRODUCTION
Fires are tragic events that happen frequently in Brazil and around the world, possessing a great destructive potential of patrimony and lives. According to the study carried out by Corrêa et al. (2015) on the occurrence of fires in the city of Recife (Pernambuco – Brazil) in years 2011-2013, about 33% of the occurrences of these events were in buildings. Of this percentage, about 40% corresponds to residential buildings, and the great majority of these events, approximately 75%, occur in single-family homes. According to the authors, this fact is worrying, since in Brazil this type of building does not have preventive normative guidelines on Fire Safety, showing the need for investment in research in this area of knowledge.
Studies of the behavior and development of fires in buildings are of importance to assist researchers in understanding this phenomenon. With these studies, it’s possible, among others, to estimate temperatures and predict the movement of smoke in burned buildings before the occurrence of the incident, helping in the development of strategies aimed at protecting the life of its occupants and the patrimony.
The computer simulation is a tool that presents great potential in the aid of studies on Building Fire Prevention (BFP), providing the researcher with a better understanding of the behavior of this phenomenon. Nowadays, the use of this tool is a common practice among researchers in this area around the world. However, in Brazil, the use of software for this purpose is still not widespread, a fact that results in a scarce availability of literature to aid in their understanding and use (Tabaczenski, et al, 2017a).
In sum, fire simulation software ‘scan be based on the zone model, such as software OZone, developed by University of Liège, and the Consolidated Model of Fire and Smoke Transport (CFAST), developed by National Institute of Standards and Technology from United States of America (NIST/EUA), or, based on computational fluid dynamics model, as the software Fire Dynamics Simulator (FDS), also developed by NIST, and the SMARTFIRE, developed by University of Greenwich.

From the fire simulation software, the SDS is the most used in technical-scientific research, and consequently the richest in available literature. Since the beginning of dissemination, in the year of 2000, it has been widely used in BFP studies worldwide. In Brazil, the first publications of research carried out with the aid of this software date back to the year of 2008 and, gradually, it has gained space in the technical-scientific environment as a tool to support studies aimed at both diagnosis and for predictions of buildings in a situation of fire.

Due to insufficient knowledge of the properties of materials (mainly combustible materials), and of complete pyrolysis and combustion behavior of these materials, there is still a need for improvements in simulation techniques in this software. Therefore, full-scale experimental fire tests are of importance to improve knowledge about the behavior of this phenomenon, allowing the comparison of measured measurements with the numerical results, in order to improve the precision of the developed models (Byström et al., 2012).

In order to demonstrate some of the potential uses of SDS in aid of BFP studies, this study aims to develop a computer model capable of reproducing the development of temperatures in the first minutes of a fire experimentally performed by Corrêa et al. (2017), in a room that represented a dormitory belonging to single-family residences typically burned in the city of Recife.

1.1 Bibliographic Review

In the world panorama, several studies of SCIE have been using experimental tests to calibrate the models of computational simulation of fires developed in the FDS (McGrattan et al., 2013; WANG et al., 2016; YU LONG-XING et al., 2018). Byström et al. (2012), carried out an experimental fire test with wood pieces under low ambient temperature in a two-story concrete building and later developed a computational model of this experiment in the FDS. The experimental results of the development of temperatures were compared with the results of the numerical simulations, showing that the developed model presented results consistent with those obtained experimentally. Yuen et al. (2014), conducted some experimental fire tests in a fully furnished dormitory and later developed a computational model of this scenario in the FDS. The analysis of the results showed that the computational model was able to provide predictions of temperature, heat flow, and propagation of fire and smoke consistent with those obtained experimentally.

Among the studies carried out in Brazil, a predominance of prognostic analyzes is noticed and there is a lack of experimental studies that can help in the validation of the developed computational models. Despite this, some studies have used experimental tests found in the literature to calibrate the models developed in the FDS. (Tabaczenski et al, 2017a)

Centeno et al. (2015) developed a computational model of a confined pool fire in a residential environment, based on an experimental study found in the literature. With this study, the authors observed that the temperature profile obtained with the FDS agreed with the experimental results, demonstrating the software's ability to reproduce the fire studied.

Tabaczenski et al.(2017b) developed a computational model of a fire in a subdivision representing an office, based on an experimental essay found in the literature. With this study the authors verified that the knowledge and application of the thermal properties not only of the combustible materials but also of the incombustible materials involved in a computational simulation in the FDS is of importance to obtain results consistent with the real situations. Therefore, the results obtained showed that, when properly calibrated, the models developed in the software can return reliable predictions of the development of gas temperatures in fire scenarios.

Numerical simulation and fire experiment in residential dormitory

R. Tabaczenski, C. Corrêa, T. Ancelmo Pires, J. J. Régo Silva
2. EXPERIMENTAL STUDY

The experimental study is presented by Corrêa et al. (2017). In this study, an analysis of the development of temperatures resulting from a fire in a room belonging to the ground floor of the Fire Fighting Training Workshop was carried out, within the Center for Teaching and Instruction of the Fire Brigade of Pernambuco. This room was adapted to reproduce a dormitory similar to those belonging to single-family dwellings typically burned in the city of Recife, according to the survey of Corrêa et al. (2016).

The fire load of this dormitory was materialized through the furniture and objects determined in the research of Corrêa et al. (2016), based on the mapping of fires in buildings in this city during the triennium of 2011-2013 conducted by Corrêa et al. (2015). Figure 1 shows the internal dimensions and furniture of this dormitory.

These furniture and objects had their dimensions and weight measured so, through the calorific potential of the predominant materials in their composition, determine the value of the fire load present in the dormitory. The calorific value of the materials was obtained through the CBMSC IN 003 (2014) and, with this, it was concluded that the fire load present in this dormitory was 499,56 MJ/m² (Corrêa et al., 2017).

The structure of this dormitory, as well as of the whole building, is reinforced concrete; the floor is simple concrete and the pre-shaped slab is lined with ceramic tiles and concrete cover. The walls of the dormitory are made of non-structural ceramic bricks, externally lined with cement mortar and internally with different materials, such as: cement slab (walls P1 e P4), plaster mortar (wall P2) e cement mortar (wall P3) (Corrêa et al., 2017).

The ignition of the fire occurred through a paraffin device for igniting fireplaces positioned under the lower bed of the bunk. For temperature gauging, 24 K type thermocouples were installed, distributed in the furniture, center and walls of the compartment as shown in Figure 2.
During the 48-minute experimental test, the window belonging to the burning dormitory was fully opened while the door remained closed for the first few minutes, causing the fire to be controlled by ventilation and to develop combustion and exhaust cycles. At 18 minutes, in order to prevent the natural extinction of the fire, the compartment door was opened, providing a cross ventilation, bringing the heat flow quickly to the compartment adjacent to the test. However, despite this strategy, there was no generalization of the fire, instead, after a few more cycles of combustion and exhaustion it went into decline until a fire fighting team of the fire department entered the environment promoting the extinguishing of the flame’s remnants and wall cooling (Corrêa, et al. 2017).

3. COMPUTATION MODEL DEVELOPED IN THE FDS

The development of the computational model in FDS was done in order to reproduce in the best possible way the experimental test carried out by Corrêa et al. (2017). The input parameters and strategies adopted to develop the model were based on the event’s chronology, geometry and specificities of the building, observation of environmental conditions and relevant technical standards.

The FDS is a CFD model-based fire simulation software that, among other things, allows the achievement of gas temperatures and solid objects, as well as graphically represent the behavior of fire propagation and smoke movement throughout the simulated building. In this software it is possible to simulate several rooms at the same time, allowing to perform analyzes not only in the room that is set on fire but also in the adjacent ones. Thus, to perform a closer analysis of reality, all the ground floor of the building used to carry out the experimental study was considered in the computational model developed in the FDS. Figure 3 shows the schematic diagram of the ground floor of the building where the experimental test took place.
Figure 3. Schematic diagram for the ground floor of the building where the experimental test took place.

Following the orientation of McGrattan et al. (2016) and, in order to analyze the flow of smoke through the openings to the outside, it was considered a computational domain that extrapolated some meters beyond the dimensions of the pavement (Figure 3), with the following dimensions: 10.0 m (axis x) x 7.5 m (axis y) x 4.0 m (axis z), with a cubic mesh of 10 cm, totalizing 300,000 elements. This way, all the geometries of the model (walls, ceiling, floor, doors, windows, ladder and combustible material) had their dimensions and positioning adjusted so that their edges were multiple of 10 cm, always occupying an entire element in the computational domain.

At the maximum and minimum ends of the x and y axes, and at the maximum end of the z axis, open surfaces called OPEN VENTS were created, indicating an opening to the exterior of the computational domain, ensuring that there is communication between the internal and external environments of the domain and fire supply with oxygen.

As initial environmental parameters, the following were considered: ambient temperature of 29.50 °C, according to the readings obtained by Corrêa et al. (2017); atmospheric pressure at sea level of 101,325 Pa; air humidity of 80% and wind speed of 3.0 m/s, as occurred on the day of the test as indicated by INMET (2017).

In the absence of parameters indicated by Corrêa et al. (2017), the thermal properties attributed to the walls, roof and floor of the building, with the exception of the Emissivity that had its value adopted, were defined according to the indications of the standard ABNT NBR 15220-2 (2005). These properties, which were assumed as constants during the simulation, are shown in Table 1.
Analogously to the experimental study, the computational simulation of the walls of the dormitory was considered with different internal coatings. Due to the impossibility of representing the roughness resulting from the cementitious slab, this was described in the software as being a layer of cement mortar with a smaller thickness than the other layers composed by this material. The thicknesses and materials that made up the layers of walls, ceiling and floor are shown in Table 2. From this table, Layer 1 is the inner layer, Layer 2 is the middle layer and Layer 3 is the outer layer to the compartment. The other walls of the building were assumed with the same characteristics of the wall P3. It should be noted that these thicknesses are independent of the dimensions of the mesh adopted.

In the absence of parameters indicated by Corrêa et al. (2017) and, due to the difficulty of obtaining thermal properties of all the combustible materials present in the experimental test, to model the fire in the room was considered a simplified strategy where the fire load was materialized by wooden rafters, distributed in the environment according to the distribution of the experimental objects, whose thermal properties were: density, thermal conductivity and specific heat, with respective values of 400 kg/m³, 0.12 W/m.K and 1.34 kJ/kg.K, defined according to the instructions of ABNT NBR 15220-2 (2005); Emissivity, with adopted value of 0.9; calorific power of 17500 kJ/kg, defined according to the indications of NP EN 1991-1-2 (2010); ignition temperature of 210 °C, according to the study by Figueroa & Moraes (2009); heat release rate of 100 kW/m², according to the study of Rocha (2014).

The geometry of the model developed for computational fire simulation in FDS is shown in Figure 4.
Numerical simulation and fire experiment in residential dormitory

R. Tabaczenski, C. Corrêa, T. Ancelmo Pires, J. J. Régo Silva

In simulations of fires in the FDS, it is necessary to define a gaseous fuel reaction that will act as a substitute for all potential fuel sources. If this reaction is not defined in the standard software library, the user can specify the chemical formulation of the fuel along with the CO, soot, and other related parameters. (McGrattan et al., 2016). In the model developed in this study, the wood fuel was represented by the chemical formulation CH\textsubscript{1.7}O\textsubscript{0.74}N\textsubscript{0.002}, yields of carbon monoxide and soot of 0.004 kg/kg e 0.015 kg/kg respectively. These yields are expressed in amount of carbon monoxide and soot emitted per unit mass of fuel consumed (Weinschenk et al., 2014).

To account for the ignition of the fire that occurred through the paraffin device in the experimental test of Corrêa et al. (2017), a burner was used similarly to the device in the experimental test. This burner was deactivated after 150 seconds, releasing approximately 0.06% of the total fire load, and had the function of only starting the fire. As a result, the increase in temperature generated a chain reaction, causing the fire to spread through the burning of the wooden rafters that combust after reaching their respective ignition temperature.

To obtain readings of the temperatures developed during the fire, some meters positioned similarly to the thermocouples were inserted in the experimental test (see Figure 2). The following thermocouples: 01 – 08 (gas in the center of the room), 09 e 10 (internal and external faces of the wall P3), 11 e 12 (inner and outer faces of wall P2), and, 13 e 14 (internal and external faces of the wall P1).

As in the experimental test, in this computational simulation the window of the burned dormitory was considered open during the whole simulation, while the door was opened only at 18 minutes. During this time, between the start of the fire and the opening of the door, in the experimental test the maximum temperatures varied between 600 °C and 800 °C. Under these temperature conditions the integrity of human life would have already been corrupted. Thus, in the comparison of the obtained results, this study was stopped at the initial minutes of the fire until the door opening, as shown below.

4. RESULTS

As in the experimental test, in the computer simulation performed through the FDS software (up to 18 minutes) there was no generalization of the fire (Flashover). This was due to the depletion of oxygen in the environment, since with the closed door there was no cross ventilation that could provide enough supply of the combustion agent for fire development. In this way, as can be observed in the Figure 5, the fire was restricted to the wooden rafters that represented the bunk present in the experimental test. In this figure the smoke was concealed for the purpose of visualizing the fire only.
As in the experimental test, it was observed that in less than 5 minutes the room was totally taken up by smoke, as can be observed in the Figure 6.

In the computational simulation the combustion and exhaust cycles were not observed as in the experimental test presented by Corrêa et al. (2017). Despite this, in general it was observed that the temperatures obtained with the developed model were close to the average temperatures obtained in the experimental test. Figure 7 shows the temperatures of the gases obtained through the thermocouple 08, positioned just below the compartment ceiling (top layer), the computer simulation in the FDS and the experimental test.
In the computational simulation, there is a rapid growth of temperatures up to 2 minutes, reaching 300 °C, after that the growth occurs more slowly until reaching the level of 500 °C at 6 minutes. In the experimental test this sudden growth occurs between 2 and 4 minutes until the dormitory is taken up by the smoke promoting a gas saturation in the environment, after which the combustion and exhaust cycles begin, culminating in peaks up to 600°C and valleys up to 360°C in temperature. This behavior is repeated at all measuring points in the center of the room. Figure 8 shows the temperatures of gases obtained through thermocouple 04, positioned at a height of 120 cm from the floor of the compartment (intermediate layer).

In the middle layer of the compartment the differences in results: experimental and computational become more discreet. It is observed that in the experimental test the maximum temperature is reached at 10 minutes with 360 °C. In this same moment in the computational simulation the measured temperature is of 300 °C.

In the lowest layer of the compartment the values are reversed. At this point, the temperatures measured through the computational simulation become larger than those measured experimentally, yet the difference between these values always remains between 50 °C and 100 °C. Figure 9 shows the temperatures of gases obtained through thermocouple 01, positioned at a height of 30 cm from the floor of the compartment (lower layer).
As seen through the Figure 7, Figure 8 and Figure 9, the computational simulation presented results of more homogeneous temperatures along the height of the compartment. From these results, it is possible to draw some temperature profiles obtained in the center of the studied compartment, as shown in Figure 10.

It is observed that, in the lower layers of the dormitory, the results of temperatures obtained through the computational simulation were generally higher than those obtained experimentally. In the upper layers this behavior is inversely, that is, the results obtained experimentally were generally higher than those obtained through the computational simulation. Although the computational simulation provides a less expressive temperature gradient, it is evident the difference between the analyzed heights. At 15 minutes of simulation, the lowest layer of the compartment (30 cm from the floor) is 220 °C, while the uppermost layer (close to the ceiling, 240 cm from the floor) is 540 °C, behavior resulting from the convection of hot gases into the environment.

Figure 11 shows the temperature profile in the XZ plane of the computational domain in the center of the flared dormitory at 15 minutes of simulation.
Through this profile it is possible to visualize the temperature gradient developed in the entire XZ plane in the dormitory due to the convection of the gases in the environment. It is evident that the maximum temperatures occur close to the window that was open. In this same place you can also see a small entrance of fresh air coming from outside the building.

As for the measured temperatures on the wall faces, due to measurement uncertainties, thermocouples were positioned analogously to the experimental test, providing the gauging of temperatures that were actually absorbed by the walls through the thermal radiation of the fire, and, in addition thermocouples were placed a few centimeters apart from their faces, allowing the measurement of temperatures in the gases close to them.

In the analysis of the results, it was verified that the temperatures captured in the computational simulation that more closely approximated those obtained experimentally were the ones measured in the gases near the walls, and not in the face of the same ones. Figure 12 shows the development of measured temperatures in the wall P3, whose inner coating was cement mortar.

In the inner face of the wall (face exposed to fire), the maximum temperatures developed were 400 °C, value very close to that obtained experimentally. In the external face of the wall, the measured temperatures, both computationally and experimentally, did not exceed 35 °C.

Figure 13 and Figure 14 show the development of measured temperatures in the walls P2 and P1, whose internal coating was gypsum mortar and cement slab respectively.
Figure 13. Temperatures measured on the wall P2: (a) internal face (thermocouple 11); (b) external face (thermocouple 12).

Figure 14. Temperatures measured on the wall P1: (a) internal face (thermocouple 13); (b) external face (thermocouple 14).

On the inner faces of the walls (faces exposed to fire), the maximum temperatures developed were approximately 700 °C, value very close to that obtained experimentally. In these measurements there is a greater oscillation in the results on the outer faces of the walls, especially on the wall P1. This fact is justified by the thermocouples being positioned near the dormitory window. Thus, due to the incidence of the wind in the place, this meter gauged the temperatures coming from the convection of the gases that left the dormitory.

In the external face of the wall P2, the measured temperatures, both computationally and experimentally, did not exceed 38 °C. In wall P1 the difference between the results was slightly higher: In the experimental test, the maximum temperature recorded was 65 °C, while in computer simulation this value was 82 °C.

5. CONCLUSIONS

This study presented the computational simulation of a fire in dormitory of single-family homes typically burned in the city of Recife (Pernambuco, Brazil), whose experimental trial was presented by Corrêa et al. (2017).

The computational simulation was performed through the FDS software and had as objective the analysis of the development of temperatures in the dormitory set fire. In view of the results presented, the following conclusions can be:

- As in the experimental test, there was no generalization of the fire due to oxygen depletion in the environment;
The computational simulation did not present cycles of combustion, intense gas production and exhaustion as in the experimental test. The occurrence of this behavior raised two hypotheses: (1) the admission of simplified strategies for model development does not contemplate all the phenomena that occurred in the experimental test, due to the absence of oxygen and excess smoke in the compartment. It should be emphasized that in the FDS there is the possibility of insertion of numerous physical-chemical properties of the materials, which allow a more accurate characterization of these in a computational simulation, however, these properties are difficult to obtain, making such refinement also difficult to execute; (2) the FDS combustion model is not suitable for scenarios in which there is no oxygen in the compartment, leading to the computational simulation under this condition to develop a behavior different from the experimental test.

In the lower layers of the dormitory, the temperature results obtained through the computational simulation were generally higher than those obtained experimentally. In the upper layers, the experimental results were generally higher than those obtained through computational simulation.

The maximum temperatures developed in the fire occurred near the dormitory window, which is the only source of supply of fire retardant in the initial 18 minutes of the experimental test.

In the center of the dormitory, the highest temperature measured was 530 °C close to the ceiling (240 cm from the floor), at 15 minutes of simulation.

On the walls, the highest measured temperatures were approximately 730 °C after 10 minutes of simulation, on the inner faces of walls P1 and P2. This behavior was already expected, since these were the closest to the initial focus of the fire.

Despite the simplified strategy adopted, the developed temperatures were close to the average temperatures obtained in the experimental test, showing that, despite not faithfully reproducing the behavior of the actual fire, the developed model was able to represent results consistent with the temperatures developed during the fire.

ABSTRACT

In order to evaluate the influence of anchorage on the flexural strength of beams strengthened with Carbon Fiber Reinforced Polymer (CFRP) sheets, the experimental results of 126 tests in the literature and of an unprecedented series with 4 reinforced concrete beams, tested by these authors, were analyzed. The parameters affecting the performance and the strength of the beams are evaluated, and the design criteria of fib Bulletin 14 (2001) and ACI 440-2R (2008) are discussed. It was observed that, even with auxiliary devices in the PRFC anchorage, premature failure is possible, and that both theoretical recommendations lead to safe estimates, but excessively conservative in cases where the anchorage of the PRFC sheet is properly done.

Keywords: reinforced concrete; flexural strengthening; CFRP sheets; anchorage.

Influência da ancoragem na resistência à flexão de vigas reforçadas com mantas de PRFC

RESUMO
Buscando avaliar a influência da ancoragem na resistência à flexão de vigas reforçadas com mantas de Polímero Reforçado com Fibra de Carbono (PRFC), foram analisados os resultados experimentais de 126 ensaios presentes na literatura e de uma série inédita, ensaiada pelos autores, com 4 vigas de concreto armado. São avaliados os parâmetros que afetam o desempenho e a resistência das vigas, e discutidos os critérios de dimensionamento do fib Bulletin 14 (2001) e ACI 440-2R (2008). Observou-se que, mesmo com dispositivos auxiliares na ancoragem do PRFC, falhas prematuras são possíveis, e também que ambas as recomendações teóricas conduzem a estimativas a favor da segurança, porém excessivamente conservadoras nos casos onde a ancoragem da manta de PRFC é feita adequadamente.

Palavras-chave: concreto armado; reforço à flexão; mantas de PRFC; ancoragem.

Influencia del anclaje en la resistencia a la flexión de vigas reforzadas con mantas de PRFC

RESUMEN
Buscando evaluar la influencia del anclaje en la resistencia a la flexión de vigas reforzadas con mantas de Polímero Reforzado con Fibra de Carbono (PRFC), se analizaron los resultados experimentales de 126 ensayos presentes en la literatura y de una serie inédita de los autores, con 4 vigas de hormigón armado. Se evalúan los parámetros que afectan desempeño y resistencia de vigas, y se discuten los criterios de dimensionamiento del fib Bulletin 14 (2001) y ACI 440-2R (2008). Se observó que, incluso con dispositivos auxiliares en el anclaje del PRFC, fallos prematuros son posibles, y que ambas recomendaciones conducen a estimaciones seguras, pero excesivamente conservadoras en los casos en que el anclaje de la manta de PRFC se realice adecuadamente.

NOMENCLATURE

- $a$: shear span
- $b_f$: width of the layer of CFRP
- $b_w$: width of the beam
- $c$: height of the block of rectangular compression equivalent of the concrete
- $c_1$: factor obtained by calibration of results (equal to 0.64 for CFRP)
- $d$: effective beam height
- $d'$: centroid position of the compressed reinforcement
- $f_c$: concrete compression strength
- $f_{ctm}$: average tensile strength of concrete
- $f_e$: effective strength of the CFRP
- $f_s$: strength in the steel of the tensile reinforcement
- $f_s'$: steel strength of the compressed reinforcement
- $f_{ys}$: yield strength of the tensile reinforcement
- $f_{ys}'$: yield strength of the compressed reinforcement
- $h$: height of the beam
- $k_b$: geometric factor
- $k_c$: constant that considers the compacting of the concrete during the concreting
- $l$: clamping width
- $l_b$: anchoring length of the CFRP sheet
- $n$: number of layers of CFRP
- $t_t$: thickness of the CFRP
- $x$: position of the neutral axis
Influence of anchorage on flexural strength of beams strengthened with CFRP sheets

1. INTRODUCTION

Among the techniques used for the strengthening of reinforced concrete structures, we highlight the systems that use Fiber Reinforced Polymers (FRP), for presenting low weight and high tensile and corrosion strength, and the Carbon Fiber Reinforced Polymers (CFRP) that have shown significant acceptance for more than two decades due to their high values of strength, stiffness and durability, as well as the ease of installation when compared to other types of fibers (Monti and Liotta, 2007). In the specific case of flexural reinforcement of reinforced concrete beams, several researchers show that the use of sheets of CFRP is an effective methodology, highlighting the works of Rafi et al. (2008), Khan and Fareed (2014) and Hawileh et al. (2015).
However, it is important to feature that premature failures are associated with its use. In the case of flexural reinforced beams, this brittle fracture may occur due to the detachment of the carbon fiber from the concrete substrate, which may limit the increase in strength provided by the reinforcement. This mode of brittle ruin is usually associated with deficiency in the anchorage of the reinforcement system, which makes the use of additional devices recommended, such as band clipping of CFRP sheet (see Benjeddou et al., 2007; Dong et al., 2011, Kim and Shin, 2011, among others).

This work presents a series of experimental tests on reinforced concrete beams strengthened with CFRP sheets, carried out with the objective of evaluating the influence of the anchorage in the reinforcement structural performance. In addition, a large database was set up, with experimental results selected from the work of different authors. This database is used to discuss the influence of different parameters on the performance of reinforcement with CFRP sheets and to evaluate the performance of theoretical predictions of strength obtained using the recommendations presented by ACI 440-2R (2008) and fib Bulletin 14 (2001).

2. CFRP STRENGTHENED BEAMS

2.1 Failure modes
Teng et al. (2003) state that beams strengthened to flexure with CFRP sheets may exhibit brittle failure modes, for instance: by exhaustion of the strength of the CFRP (see Figure 1a); detachment of the reinforcement at the interface with the concrete (see Figure 1b); and separation of the reinforcement together with the concrete covering of the flexural reinforcement (see Figure 3c). The failure of the CFRP sheet can occur in weakly reinforced beams by flexure, being a brittle mode of failure since the CFRP presents linear-elastic behavior until the failure. The detachment of the sheet may occur due to lack of the anchorage of reinforcement, excessive cracking of the beam or, faults in its bonding process. The separation of concrete cover layer can be caused by shear strengths at the interface between concrete and CFRP due to the difference between the moduli of elasticity of these materials, which can be amplified by the corrosion of the bending reinforcement.

![Figure 1. Failure modes of beams strengthened to flexure with CFRP.](image)

2.2 Flexural Strength
The behavior of a reinforced concrete beam strengthened with CFRP and subjected to bending can be expressed according to the diagram of Figure 2. In this analysis, it’s considered that the ratio of the reinforced beam framework is equivalent to the sum of the initial reinforcement rate with contribution from the reinforcement, as presented in (1).
Influence of anchorage on flexural strength of beams strengthened with CFRP sheets

Figure 2. Stress-strain diagram of a beam strengthened with CFRP.

\[
\rho_r = \rho + \frac{A_f \cdot E_f}{b_w \cdot h \cdot E_s}
\]  

Where: \(\rho\) is the rate of the reinforcement of the beam before the strengthening; \(A_f\) is the area of reinforcement applied to the beam; \(E_f\) is the modulus of elasticity of the CFRP; \(E_s\) is the modulus of elasticity of steel; \(b_w\) is the width of the beam; \(h\) is the height of the beam.

2.2.1 ACI 440-2R (2008)

The American code ACI 440-2R (2008) presents recommendations for the sizing of reinforcement using CFRP. To determine the flexural strength of reinforced concrete beams reinforced with carbon fiber sheets, (2) - (10) are used.

\[
\varepsilon_{fu} = 0.41 \sqrt{\frac{f_{c}}{n \cdot E_{f} \cdot f_{f}} < 0.9 \cdot \varepsilon_{fu}}
\]

\[
\varepsilon_{fc} = \varepsilon_{cu} \left(\frac{h - x}{x}\right) - \varepsilon_{mi} \leq \varepsilon_{jd}
\]

\[
f_{fe} = f_{f} \cdot \varepsilon_{fe}
\]

\[
\varepsilon_{s}' = \varepsilon_{cu} \left(\frac{x - d'}{x}\right)
\]

\[
\varepsilon_{s} = \varepsilon_{fc} \left(\frac{d - x}{h - x}\right)
\]

\[
f_{s}' = E_{s} \cdot \varepsilon_{s}' \leq f_{ys}'
\]

\[
f_{s} = E_{s} \cdot \varepsilon_{s} \leq f_{ys}
\]

\[
x = \frac{(A_{f} \cdot f_{f}) + (A_{f} \cdot f_{fe}) - (A_{f} \cdot f_{s}')}{\beta_{1} \cdot 0.85 \cdot f_{c} \cdot b_{w}}
\]
Influence of anchorage on flexural strength of beams strengthened with CFRP sheets

\[ M_R = A_s \cdot f_{s'} \left( d - \frac{\beta_1 \cdot x}{2} \right) + 0.85 \cdot A_f \cdot f_{f_e} \left( h - \frac{\beta_1 \cdot x}{2} \right) + A_s' \cdot f_{s'} \left( \frac{\beta_1 \cdot x}{2} - d' \right) \]  

(10)

Where: \( \varepsilon_{fd} \) is the limit value of fiber strain to be adopted in the sizing and verification of reinforcement to avoid premature fiber failure; \( n \) is the number of layers of CFRP; \( t_r \) is the thickness of the CFRP; \( \varepsilon_{fu} \) is the ultimate strain observed in the polymer at the moment of failure; \( \varepsilon_{fe} \) is the effective strain in the CFRP; \( x \) is the position of the neutral axis; \( \varepsilon_{bi} \) is the strain found in the covering of the tensile reinforcement in the beam before the strengthen; \( f_{fe} \) is the effective strength of the CFRP; \( d \) is the effective beam height; \( \varepsilon_s' \) is the strain in the compressed reinforcement; \( f_s \) is the strength in the steel of the compressed reinforcement; \( d' \) is the centroid position of the compressed reinforcement; \( A_s \) is the steel area of the tensile reinforcement; \( A_s' \) is the steel area of compressed reinforcement; \( \beta_1 \) is a coefficient that determines the approximation of the resultant compression curve of the concrete to a rectangle, being 0.85 for concrete with \( f_c \) values lower than 28 MPa and there being a linear decrease of 0.05 for each 7 MPa above that limit of strength, the minimum value for such a coefficient, according to ACI 318 (2014), is 0.65; MR is the tough moment in the cross section of the beam.

2.2.2 fib Bulletin 14 (2001)

The fib Bulletin 14 (2001) presents recommendations for the dimensioning of flexural reinforced beams with CFRP and adopts a calculation philosophy like that adopted by ACI 440-2R (2008). The same equations presented by the ACI are used in this document, differentiating only the following parameters: the coefficient \( \beta_1 \) in it is called of \( \psi \) and equals to 0.8, independent of the class of strength of the concrete; and the strain limit of the fiber, which is calculated by (11), whose parameters are found by means of (12) - (14).

\[ \varepsilon_{\text{fib}} = \frac{N_{fa,max}}{E_f \cdot A_f} \]  

(11)

\[ N_{fa,max} = \alpha \cdot c_1 \cdot k_c \cdot k_b \cdot b_w \cdot \sqrt{E_f \cdot t_f \cdot f_{ctm}} \]  

(12)

\[ k_b = 1.06 \left( \frac{b_f}{b_w} \right) \geq 1 \]  

(13)

\[ f_{ctm} = 0.33 \cdot \sqrt{f_c} \]  

(14)

Where: \( N_{fa,max} \) is the maximum force that can be applied to the reinforcement of the beam (expressed in N); \( \alpha \) is a reduction coefficient due to the propagation of inclined cracks, adopted as 0.9; \( c_1 \) is equal to 0.64; \( k_c \) is a constant that considers the compacting of the concrete during the concreting, being this value equal to 1 when the strengthening is applied in the underside of the beam and 0.67 in the upper face; \( k_b \) is a geometric factor; \( f_{ctm} \) is the average tensile strength of concrete, as expressed in Eurocode 2 (2004); \( b_f \) is the width of the layer of CFRP.
3. EXPERIMENTAL PROGRAM

3.1 Characteristics of the beams
Tests were carried out on 4 reinforced concrete beams strengthened with CFRP sheets, having as variables the sheet anchorage length and width in order to evaluate their influence on both the performance and the strength of the beams. It was tested 1 reference beam without reinforcement and 3 reinforced beams with carbon fiber sheet. The rates of steel reinforcement and CFRP were kept constant. Table 1 and Figure 3 show the main characteristics of the beams. The strains in the flexural reinforcement, the reinforcement sheet and the clamping were monitored with electrical extensometers, as shown in Figure 4. Figure 5 shows the test system of the beams.

![Figure 4. Monitoring of beams.](image)
3.2 Discussion of Results

The failure mode of each of the beams tested can be visualized in Figure 6. It was observed that the reference beam failed by flexure after its longitudinal reinforcement reached high levels of strain (Figure 6a). In the V2 beam the concrete was pulled out in the zone adjacent to the clamping (Figure 6b). The V3 beam lost its strength after the fiber detachment occurred in part of the clamping contact zone (Figure 6c). However, the V4 beam failed after the detachment of the concrete covering in the region of the flexure span (Figure 6d).

Figure 7 shows the results of strains measured in the flexural reinforcement and at different points of the PRFC. It is noticed that, in all the beams, the flexural reinforcement reached the yielding, as shown in Figure 7a. The strains in the flexural reinforcement were smaller in the beams with the sheet of CFRP for the same load levels, since the reinforcement contributed in the tensile part of the piece. In addition, it was observed that the resistant behavior of the beams with the sheet was more brittle than that of the non-reinforced beam, since after reaching the maximum strength, the readings were interrupted by the failure of the part, whereas in the beam V1, if the maximum load was reached, this loading level remained associated to a high level of strain. Figure 7b shows that...
both the anchoring length of the fiber and the clamping width influenced the ultimate strain of the CFRP measured in the tests, varying from 3.5 ‰ for the beam V2 to approximately 4.2 ‰ for the beams V3 and V4. In all cases, it should be noted that these values are higher than theoretically predicted by the ACI, which would be 1.9 ‰. It should be emphasized that none of the beams failed with the exhaustion of the tensile strength of the sheet of CFRP. Figure 7c shows that in all the beams the level of strain at the end of the reinforcement was smaller than that measured in the middle of the span, where the moment is maximum and that in the case of the beam V2, which failed due to the detachment of the fiber in this region, the strain limit measured was practically the same as that suggested by the manufacturer of 2.1 ‰. In Figure 7d it is possible to notice that the level of strain developed in the region of the clamping was small and that in beam V3 it clearly begins to separate before the failure.

Figure 7. Results of the beams tests.

Figure 8 shows the vertical displacement curve of the beams, measured in the middle of the span. It is possible to notice that the reinforced beams presented a very similar response, showing greater rigidity than the reference beam, which failed by flexure in a ductile manner and showed large displacements when reaching the moment of yield of its flexural reinforcement. As seen, all the reinforced beams failed abruptly, with failure occurring in different regions of the CFRP.
Influence of anchorage on flexural strength of beams strengthened with CFRP sheets

4. DATABASE

4.1 Methodology of collection and analysis of data

In addition to the experimental program, a database was collected with the results of 126 tests of 20 authors, involving flexural reinforced beams with the sheet of CFRP. As a criterion for the choice of beams, only those that failed by bending, without initial loading and externally bonded reinforcement, were selected. The objective of this data analysis is to evaluate the influence of the main variables on the flexural strength of reinforced beams with CFRP.

The analysis of the database involves the comparison of the experimental results with the theoretical estimates obtained using the ACI and fib 14. Thus, it was calculated the values of average, coefficient of variation and standard deviation of the ratio between the experimental ultimate moment and the theoretical resistant moment ($M_u/M_{Rteo}$), and finally, the percentage of safety results ($M_u/M_{Rteo} < 1$) was evaluated. In order to evaluate the precision of the theoretical models, graphs are presented that compare the moment of experimental failure ($M_u$) by the function of the predicted resistant moment ($M_{Rteo}$), in order to analyze if the tendency of the obtained results approaches the ideal condition ($M_u=M_{Rteo}$).
As previously noted, the performance of the reinforcement with sheet of CFRP is directly related to the quality of fiber anchoring to concrete. Therefore, the beams of the database were divided into 3 groups: group 1 for situations where the bonding of the sheet stretched from the center of the beam to the support or beyond; the group 2 with beams in which the glue of the sheet did not extend to the support; and the group 3 with beams in which external devices were used to aid in reinforcement anchorage, such as screws or restrainers. It should be noted that this type of anchorage is considered by several authors as the most favorable for anchoring the CFRP sheet, since that the device is made of the same material.

Another method used was the Collins (2001) criterion, known as Demerit Points Classification (DPC), in which the values of $M_d/M_{Reo}$ were classified in ranges from "extremely dangerous" to "extremely conservative", with performance of the theoretical model defined as a number resulting from the sum of the products from $M_d/M_{Reo}$ by their corresponding score, according to the classification. Table 3 presents a summary of the characteristics of the beams of the database, as well as the symbology used by the authors to identify the figures. Table 4 shows a summary of the variables related to the reinforcement with carbon fiber sheet of the beams of the database. Table 5 presents the parameters related to Collins DPC (2001).

Finally, were prepared graphs which relate the experimental strength of the beams to the predicted theoretical failure ($M_d/M_{Reo}$) according to the number of layers of CFRP sheets, as well as the reinforcement ratio after strengthening in relation to the initial reinforcement ($\rho_r/\rho$). The purpose of these charts is to analyze if the hypotheses adopted by the theoretical models present adequate correlation with the existing experimental evidence.

4.2 Discussion of Results

Figure 9 shows the graphs that confront the experimental strength of the database with the theoretical predictions, including in red, the experimental results tests of this research. It was observed that the two theoretical models presented similar performance in relation to the average of the results, but with f_{ib} 14 showing greater dispersion and higher percentage of results against safety. Moreover, the tested beams fit well in the trend of results observed for the larger universe generated by the database.
In order to evaluate the influence of the type of anchorage of the reinforcement with CFRP in the performance of the theoretical predictions, Figure 10 divides the general data presented in Figure 9, classifying them by type of anchorage in 3 distinct groups. For group 1, ACI presented an average closer to 1.0, as well as a lower dispersion of results and approximately the same number of values against safety, when compared with fib 14. In group 2, this behavior was reversed, and fib 14 showed lower average, but still with greater dispersion and greater percentage of results against the safety. For the beams of group 3 the theoretical methods presented similar performance, with the ACI showing again less dispersion.

As seen, using Collins criterion (2001), it is possible to establish scores for the two recommendations, based on the sample space of the collected database, as shown in Figure 11. It is observed that the ACI presents a lower penalty according to the criterion adopted.
The influence of anchorage on flexural strength of beams strengthened with CFRP sheets

Figure 10. Analysis of the theoretical models accuracy in relation to the anchorage type.

Figure 11. Result of the Collins criterion (2001).

Figure 12 analyzes the influence of the number of layers of CFRP on both reinforcement performance and theoretical methods. It is noticed that there is a trend of more conservative results as the amount of layers increases, which is justified by the fact that both recommendations limit the strain of CFRP. For the ACI, this trend is slightly higher, since in its equation the number of layers is used, which penalizes the strength estimation of reinforced beams with a high number of layers. In contrast, in fib 14 this factor is not considered.
Influence of anchorage on flexural strength of beams strengthened with CFRP sheets

Figure 12. Influence of the number of strengthening layers.

Figure 13 shows the influence of the proportion between the reinforcement ratio after the strengthening and the flexural reinforcement ratio \( \rho_r / \rho \). There is a trend of less conservative results as \( \rho_r / \rho \) increases, and for values above 1.4, ACI tends to stabilize this trend, avoiding estimates of strength against safety. However, the same was not observed for fib 14, whose predictions approached the dashed line, which expresses the limit of the design strength.

Figures 12 and 13 show that the number of layers of CFRP is not necessarily a parameter that should be penalized in the prediction of strength of flexural reinforced beams with sheets of CFRP as defined by the ACI. This is evident from, for example, the results of Beber et al. (2000), who tested beams with up to ten layers of CFRP sheets and obtained good performance, and those of Bilota et al. (2015), whose beams tested had only one or two layers of CFRP and showed much lower performance. By analyzing Figure 13, the beams of Beber et al. (2000) present low values of \( \rho_d / \rho \) while those of Bilota et al. (2015) presented extreme values within the beams of this
database, evidencing that $\rho_l/\rho$ is a fundamental parameter to be taken into consideration in the design.

5. CONCLUSION

In order to observe the influence of reinforcement anchorage with CFRP on the behavior of beams resisting to flexure, an experimental study was carried out, involving tests on 4 reinforced concrete beams, varying the anchorage criteria of the carbon fiber sheets. In addition to the experimental approach, a database with results from several authors was used to evaluate the influence of different parameters on the strength of reinforced beams to flexion with CFRP sheets. These data were also used to discuss the performance of the theoretical methods proposed by fib Bulletin 14 (2001) and ACI 440-2R (2008).

As for beam tests, it was observed that the clamping width had a greater influence on the flexural strength of the reinforced beams with CFRP sheet, since the V4 beam presented the greatest strength in relation to the others, even though the anchoring length was identical to the one of the beam V3. The beams V2 and V3 presented the same values of strength, although the beam V3 presented a greater length of anchorage between them. Another important point is that, even with the strength additions of the reinforced beams in relation to the reference, the beams with CFRP sheet have failed prematurely. Finally, it was observed that the limit values of strain of the CFRP sheet assumed by the manufacturer are very conservative in face of the experimental results recorded in this research.

As for the evaluation of the theoretical models, it is verified that both the fib 14 and the ACI presented conservative results in relation to the $M_u/M_{Rteo}$ ratio, which in practice should guarantee predictions of strength in favor of safety in most cases. It was also observed that the procedure of reducing reinforcement efficiency by means of limitations on CFRP strains, although generally in favor of safety, may become excessively conservative in cases of reinforcement where CFRP anchorage is performed properly. Finally, it is emphasized that among the evaluated parameters that affect the flexural strength of beams with CFRP sheets, it is worth noting that the ratio $\rho_l/\rho$ was more relevant than the number of layers of CFRP sheets, considering the data of this database.

6. ACKNOWLEDGMENTS

For the support on this and other researches, the authors thank: the Federal University of Pará (UFPA); to the Nucleus of Amazonian Development in Engineering (NDAE); to the Nucleus of Applied Structural Modeling (NUMEA); to the University Campus of Tucuruí (CMTUC); to Eletrobras Eletronorte; to VIAPOL Ltda for donating the reinforcement material used in the experiments; and the development agencies CNPq, CAPES and FAPESPA.

DOI: http://dx.doi.org/10.21041/ra.v9i1.259

ABSTRACT
This article aims to compare two techniques of structural reinforcement, carbon fiber and steel sheets, used for the recovery of reinforced concrete elements degraded by fire. It simulates the deterioration of a beam in a fire situation from a thermal numerical modeling and then the mentioned reinforcements are calculated. The carbon fiber required a smaller area compared to that for the steel sheet, due to its high mechanical resistance. As limitations, it is mentioned that the study is preliminary and involves only a thermal analysis of the beam, not considering the loading and its implications. It is concluded that the carbon fiber presents greater advantages with respect to reinforcement of beams.

Keywords: reinforced concrete beam; structural reinforcement; carbon fiber; bonded-in steel sheets.

Contribución a las vigas de hormigón armado degradadas por la acción del fuego: Análisis comparativo entre el refuerzo estructural con fibras de carbono y chapas metálicas

RESUMEN
Este artículo tiene como objetivo comparar dos técnicas de refuerzo estructural, fibra de carbono y chapa metálica, utilizadas para la recuperación de estructuras de hormigón armado degradado por el fuego. Se simula un deterioro de una viga en situación de incendio a partir de un modelaje numérico térmico y, en seguida, se calculan los refuerzos mencionados. La fibra de carbono exigió un área menos en comparación con la chapa metálica, debido a su elevada resistencia mecánica. Este es un estudio preliminar que envolvió solamente un análisis térmico de una viga, sin tener en cuenta el cargamento actuante y sus implicaciones. Se concluye que la fibra de carbono presenta mayores ventajas en lo que se refiere al refuerzo de vigas.

Palabras clave: viga de hormigón armado; refuerzo estructural; fibra de carbono; chapa metálica; pegadas; incendio.

1. INTRODUCCIÓN
The design of a structural project is a very complex task since, in addition to the steps of launching, designing and detailing the structural elements, the designers must foresee measures that avoid or hinder the occurrence of pathological manifestations. In general, structures are designed for a 50-year life. For this to be achieved, preventative actions must be taken, which prevent the resistant capacity of the structural elements from being lost in the short term. An example of preventative action corresponds to the waterproofing of the exposed surface of the structural component to the external environment. It acts as a mechanical barrier that prevents the entry of harmful substances or even substances that result in chemical reactions whose products are damaging, inside the structural elements.

In elements of reinforced concrete, a type of very common pathological manifestation that promotes the degradation of the structural element is the spalling. It may occur at room temperature due to corrosion of the submerged framework inside the concrete, for example (Stukovnik et al., 2019).
Contribution to the reinforced concrete beams degraded by fire: Comparative analysis between structural reinforcement with carbon fibers and steel sheets

Y. S. Simões, C. F. R. Santo

2014). In this context, Wang et al. (2013) define that the deterioration of reinforced concrete structures occurs in two stages. In the first one, there is the degradation of the protective barrier of the reinforcement, allowing the aggressive agents to enter the element. In this process, called depassivation, the structural element does not lose its resilient capacity. Regarding the second step, the deterioration of the structural element itself occurs, in which the process of corrosion of the reinforcement is initiated, followed by the spalling of the concrete surface and, later, the collapse of the structural element.

In addition to the aggressive agents, actions like fire and explosions can also lead to degradation of structures. Currently, due to the increase in the number of cases of residential buildings in a fire situation, many designers have admitted that the design of structures at room temperature, although essential, is not enough to meet the structural safety criteria. Thus, the structural elements must also be designed to meet the required fire resistance time (Kobes et al., 2010).

In everyday life, the risk of fire is imminent. It may be caused by a short circuit of an appliance, improper electrical wiring or gas leakage. In the context of the study of structures submitted to fire, it is essential to know the curve that characterizes the evolution of the temperature of the gases over time, responsible for heating the structural element. It should be noted that no fire is the same as the other, since there are many parameters involved to determine the temperature evolution of the structural element, such as: degree of ventilation of the structure, type and amount of fire load. In this regard, it becomes difficult to define an average temperature and time that residential buildings commonly reach when they are in a fire situation. Thus, the technical standards allow the adoption of a standard heating curve for the construction of models in experimental analysis. This is the standard fire model; whose standardization allows the treatment of the fire in a simpler and more approximate way.

On reinforced concrete structures, concrete acts as a thermal barrier reducing the flow of heat to steel. This is because concrete presents better thermal properties compared to other materials, such as low thermal conductivity and high specific heat, which decrease heat propagation into the cross section. In any case, because there is a heating, both materials tend to lose rigidity and mechanical resistance. Ingham (2009) explains the mechanisms of microstructural degradation of concrete in a fire situation. When the temperature of the material reaches about 100°C, the free water present in the aggregates and in the matrix evaporates, increasing the capillary porosity. At this moment, there is a small loss of resistance of the material. When the temperature rises and reaches 300°C, there is a loss of water bound to the cement matrix. Up to 600°C, the aggregates undergo thermal expansion and there is an increase of internal tension. Between 600°C and 800°C the carbonate constituents undergo decarbonation and, in the range of 800°C to 1200°C, the components disintegrate, and the concrete is calcined.

Kodur and Agrawal (2016) studied the mechanisms of failure in structural elements under fire. They explain that the deterioration of a structure is due to both the disintegration of parts of the concrete (spalling) and consequent elevation of the temperature in the steel bars, as well as the appearance of permanent deformations induced by the heating of the materials.

According to Deeny et al. (2008), the spalling that occurs in structures exposed to fire can have three origins. The first origin relates to the collapse of the aggregate near the heated surface, the second one to the disintegration of the corners of the concrete and the third to the fragile rupture of the heated surface due to the appearance of internal stresses from the evaporation of the free water. While the first origin is responsible only for surface damage and therefore does not affect the resistant capacity of the material, the second and third ones promote disintegration of concrete parts, leading to loss of mechanical strength (Khoury, 2000; Hertz, 2003).

After the fire it is necessary to evaluate if there was damage in the resistant capacity of the structural elements. If it has occurred, it should be checked the extent of it and thus choose either to destroy the structure or to recover the structural elements. The latter alternative can be achieved using
structural reinforcement techniques, in order to restore the bearing capacity of the degraded structure (Reis, 1998). Among the current reinforcement techniques and those of particular interest for this work are the bonding of steel sheets and that of carbon fiber reinforced polymers on the concrete surface. Both were chosen because they present little increase of the useful section of the structural element and do not require, in the constructive process, concreting (Obaidat, 2011). Despite the research done so far, with authors such as Lin and Zhang (2013), Firmo et al. (2015) and Jiangtao et al. (2017), who investigated the behavior of several types of reinforcement when exposed to high temperatures, none of them present reinforcement design for fire-retarded reinforced concrete structures. In addition to the behavior of the structural elements under high temperatures, it is important that the designer knows how to dimension the structural reinforcement for the situation described. Thus, this work proposes a comparative study between the two types of reinforcement previously mentioned, to be used in reinforced concrete beams degraded by the action of the fire and designed subject to flexure. Therefore, the thermal gradient was defined inside the beam, from a numerical modeling and the necessary reinforcement was calculated so that the structure returned to the resistant capacity for which it was dimensioned.

2. STRUCTURAL REINFORCEMENT

2.1. Reinforcement with carbon fibers

According to Fard (2014), the use of carbon fibers as structural reinforcement is more advantageous than the adoption of bonded-in steel sheets. This is due to the high rigidity and mechanical strength of the carbon fibers, which, together with their low specific mass, promotes an increase in the bearing capacity of the structure without adding its final weight. Moreover, corrosion resistance also represents an advantage of carbon fibers over bonded-in steel sheets. Among the disadvantages of using carbon fibers are the high cost and low performance of the fibers when subjected to fire.

In general, the carbon fiber reinforcement system is composed of two main elements: the carbon fiber, which is the element responsible for the mechanical resistance of the system, and the epoxy matrix (Figure 1), formed by epoxy resin resulting from the combination of epichlorohydrin and biphenol. The epoxy matrix is responsible for the transfer of the tensile stresses in the structure to the carbon fibers, being made by both friction and adhesion (Machado, 2007). The matrix involves all the carbon fibers present in the reinforcement, providing both mechanical strength and resistance to the aggressive agents that can deteriorate the fibers. Fard (2014) points out that the surface must be clean, free of powdery materials and the finish should be planned in order to prevent loss of adhesion between the resin and the concrete surface.

Regarding the executive process, the carbon fiber application system consists of five stages. Initially, the concrete surface is prepared by inserting a primer layer, whose function is to form a stable base free of dust and contaminants. Afterwards, the surface is regularized leaving it free of protrusions for later application of the carbon fiber. Then, the epoxy resin is applied followed by the carbon fiber blanket and the resin again. Finally, in order to protect the parts exposed to the sun against UV radiation, a finishing layer is made with acrylic paint.
Contribution to the reinforced concrete beams degraded by fire: Comparative analysis between structural reinforcement with carbon fibers and steel sheets

Y. S. Simões, C. F. R. Santo

2.2. Reinforcement by the addition of bonded-in steel sheets

The other object of study of this work corresponds to the technique of reinforcement by bonding thin steel sheets to the concrete surface. Its principle consists basically in the creation of a structural system composed of concrete-glue-steel, in which thin steel sheets are bonded, by means of epoxy resin and/or screws, to the surface of the concrete, significantly increasing the resistance of the element stresses, bending moment and shear stress.

Souza (2008) and Adorno et al. (2000) state that the bonding of the sheets to the structure can be done by means of epoxy resin applied in the area of contact between the element and the sheet (Figure 2a), or by metal screws with epoxy resin injection in the holes (Figure 2b), where the former is the most widely adopted solution in the market. This is due to both the greater ease of execution and the lower probability to be further weakened, due to holes, an already degraded structure. It is

Regarding the arrangement of the described system, the fibers should be oriented in the direction of the tension lines that they fight. Machado (2002) describes that fibers besides having a high tensile strength, have good shear strength, albeit to a lesser extent than the previous one. For the latter situation, the reinforcement is positioned in the regions of the supports in order to counter the shear stress.

According to Chowdhury et al. (2008) and Raoof and Bournas (2017), one of the main concerns in the use of carbon fiber reinforcement in structural elements is related to their combustibility. At high temperatures, the resin responsible for attaching the carbon fiber blanket to the concrete tends to degrade, generating toxic smoke and increasing the size of the flames. Wang et al. (2003), Forter and Bisby (2005) and Chowdhury et al. (2008) point out that when the temperature in the reinforcement reaches that corresponding to the glass transition of the resin, around 93ºC, the degradation of its mechanical properties begins. In addition to the mechanical resistance, the authors verified that, for temperatures higher than the glass transition of the resin, there was a reduction of the adhesion between the reinforcement and the concrete.

There is no definition in the literature about the temperature at which the total degradation of the mechanical properties of the reinforcement occurs, commonly called critical temperature. Chowdhury et al. (2008) points out that it occurs between 300ºC and 400ºC, which corresponds to the combustion temperature of the resin. On the other hand, for Kumahara et al. (1993) and Wang et al. (2003) this critical temperature is around 250ºC. Despite these heterogeneous values, Tanano et al. (1997) found that the critical temperature depends on the resin composition used in the reinforcement. These authors identified in their tests two critical temperatures depending on the type of resin used, 250ºC and 860ºC.

Another advantage of carbon fiber reinforcement is its residual strength after exposure to high temperatures. Forter and Bisby (2005) found that when the reinforcement is exposed to a temperature of up to 300ºC and then cooled to room temperature, it recovers its mechanical strength and stiffness.
emphasized that the epoxy adhesive is of extreme importance for the process, because it is through it that the stress transfer takes place, causing the old part and the reinforcement to act as a single body in a situation of perfect adhesion. (Reis, 2001).

![Figure 2. Reinforcement with steel sheet: a) fastening with resin; b) fastening with resin application into holes](image)

Like any material, its use has advantages and disadvantages. As benefits, the efficiency and the low cost stand out and associated with the fast and simple execution are a good alternative when it is necessary to reinforce the structure in a short time. Furthermore, it results in little interference in the architecture, since the reinforced section has only small geometric changes, which generates a great acceptance in the market. The disadvantages are the steel corrosion, low fire resistance, the need for struts and the difficulty to handle it, due to the weight and commercial sizes of the sheets. Branco (2012) recommends the application of fire and corrosion protection after the design of the reinforcement, since the steel sheets are not resistant to these pathologies and, besides that, the epoxy adhesive deteriorates at temperatures higher than 60°C.

### 3. DESIGN OF THE STRUCTURAL REINFORCEMENT SUBJECT TO FLEXURE

In a similar way to the flexural theory of reinforced concrete beams described in the Brazilian Standard (NBR) 6118:2014, the structural reinforcement calculation consists of a balance of the internal forces so that the resistant moment of the element is greater or equal to the present bending moment. Figure 3 shows the balance of forces and deformations for a reinforced concrete beam with strengthening at the bottom.

The calculation begins with the definition of the type of crack that the reinforced concrete element will present in the rupture. Hence, it is necessary to adopt the relation between the depth of the neutral axis (x) and the useful height of the element (d), since this parameter determines if it will be a fragile or ductile failure. For reinforced concrete elements with $f_{ck}$ up to 50 MPa, NBR 6118:2014 limits this value to 0.45 for the structure to show collapse with prior notice. Thus, the tensile stresses of the concrete ($F_c$), of the positive steel ($F_s$) and negative steel ($F'_{s}$) and of the structural reinforcement are calculated, applying the weighting coefficients defined by the international standards.
In which:

- \( b_w \) - Beam base;
- \( h \) - Beam height;
- \( d \) - Distance from the most compressed fiber to the center of gravity of the positive reinforcement;
- \( d' \) - Distance from the most compressed (tensioned) fiber to the center of gravity of the negative reinforcement (positive);
- \( x \) - Distance from the most compressed fiber to the neutral axis;
- \( A_s \) - Area of positive reinforcement (tension);
- \( A_{s'} \) - Area of negative reinforcement (compression);
- \( A_r \) - Area of reinforcement;
- \( \varepsilon_c \) - Concrete deformation;
- \( \varepsilon_s \) - Positive reinforcement deformation;
- \( \varepsilon_{s'} \) - Negative reinforcement deformation;
- \( \varepsilon_r \) - Reinforcement deformation;
- \( F_c \) - Resultant force from the compressed section of the concrete;
- \( F_s \) - Resultant force from the tensioned section of the positive reinforcement;
- \( F'_{s'} \) - Resultant force from the tensioned section of the negative reinforcement;
- \( F_r \) - Resultant force from the tensioned section of the reinforcement.

After calculating the tensile stresses of the materials, it is performed the sum of the bending moment in relation to the reinforcement application (point A of Figure 3), where the reinforcement and glue thickness are neglected for their fastening. The bending moment found at this point is valid for any other location of the beam and will be pertinent to the designing if it presents a value greater than or equal to the requested one. However, if this value is much larger than the requested bending moment, the crack mode and the position of the neutral axis initially settled are not adequate because they do not lead to an economical solution.

If the value found is acceptable, it is set the resistant bending moment in relation to the cross-section points B and C in Figure 3. As in point A, these values should be matched to the requested bending moment. The equations for calculating the moments at points A, B and C are described below.
Contribution to the reinforced concrete beams degraded by fire: Comparative analysis between structural reinforcement with carbon fibers and steel sheets

Y. S. Simões, C. F. R. Santo

\[ M_A = F_c(h - 0.4x) + F'_s(h - d') - F_s(h - d) \]  
\[ M_B = F_c(d - 0.4x) + F'_s(d - d') + F_s d' \phi \]  
\[ M_C = F_s(d - 0.4x) + F'_s(0.4x - d') + F_s \phi(h - 0.4x) \]

The coefficient \( \phi \) represents the reduction factor applied only when the reinforcement is the carbon fiber. It is adopted \( \phi = 0.85 \), as suggested by ACI 440.2R: 2008. From equations (2) and (3) we find two values for the force of reinforcement \( (F_r) \) which, by equilibrium, must be equal. This force will be used to calculate the required reinforcement area, from equations (4) and (5).

\[ A_r = \frac{F_r}{f_r} \]  
\[ f_r = \varepsilon'_r \cdot E_r \leq f_{ru} \]

In which:
- \( f_r \) - It is the tensile strength of the reinforcement;
- \( E_r \) - It is the elasticity modulus of the reinforcement, provided by the material manufacturer;
- \( \varepsilon'_r \) - It is the deformation of the reinforcement material, found by:

\[ \varepsilon'_r = \varepsilon_r - \varepsilon_{bi} \leq \varepsilon_{ru} \]

Such as:
- \( \varepsilon_r \) - It is the deformation of the reinforcement found by the linear behaviour of the deformations according to the position of the neutral axis (x);
- \( \varepsilon_{bi} \) - It is the pre-existing deformation in the steel located at the bottom of the beam, the result of its previous loading, as described by Machado (2002).

Also, according to Machado (2002), to know the level of tension, which will be reinforced during its application, it is necessary to identify the existing deformation in the structure to be reinforced. Therefore, the pre-existing deformation in the lower face of the beam \( (\varepsilon_{bi}) \) is verified. This deformation can be calculated from its permanent load when the element is strutted during the application of the reinforcement, or its entire working load, in case the strutting is not chosen. It is worth mentioning that, if the calculated resistant moment of the structural element is lower than the requested one, the position of the neutral axis is changed, and the process described above is restarted. It is, therefore, an iterative method.

4. MATERIALS AND METHODS

The study consists, initially, in the numerical representation of a beam with a span of 6.0m and cross section shown in Figure 4, degraded by the action of fire. Next, the two types of reinforcements studied here, steel sheets and carbon fibers, will be designed with the purpose of recovering the initial resistant capacity of the beam.
The concrete adopted for the beam under study has $f_{ck}$ equal to 30 MPa and steel of type CA50, whose modulus of elasticity is equivalent to 210 GPa. According to the calculation methods presented in NBR 6118:2014, the structural element was designed to resist a requested bending moment of 265.7 kN.m. Attention is drawn to the kind of crack that the beam presents. It lies in the deformation domain 2, where the steel has a maximum deformation of 1%, while that of the concrete ranges from zero to its limit, which is equal to 0.35%.

In order to represent the fire's action on the beam, a numerical model was developed using the ABAQUS computational code, which allows the solution of engineering problems, including structures at high temperatures, based on the Finite Element Method theory.

The behavior of a reinforced concrete beam under fire is complex and goes beyond the reduction of the mechanical properties (strength and stiffness) of steel and concrete. There is, for example, the previously described phenomenon of spalling, which causes the cross section to lose part of the concrete thickness when it reaches the temperature range 375-425 °C (Deeny et al., 2008). In addition, during the fire, since the steel and the concrete present different coefficients of thermal expansion, there may be longitudinal cracks in the contact between these materials.

Considering the situation presented above, for the case study presented in this work we will adopt some simplifications for the design of the reinforcement, which are described below:

1. The thermal numerical modeling will be used only to obtain the temperature field formed in the cross section. From the thermal gradient caused by the low thermal conductivity of the concrete, an average temperature representative of the beam heating will be calculated, which will be used to calculate the reduction of the mechanical properties of the materials.
2. A displacement of 1.5 cm in thickness shall be considered throughout the cross section of the reinforced concrete beam to represent the spalling.
3. The reinforcement will be calculated for the new cross section, admitting the decrease of the mechanical properties of concrete and steel. The requested moment that the degraded element must support corresponds to the one for which it was initially designed, that is, 265.7 kN.m.
4. The post-fire behavior of the reinforced concrete beam shall not be considered in the analysis.
5. It is assumed the perfect adhesion between the concrete, the framework and the reinforcement to be used.
6. It is not allowed changes in the ultimate deformations of concrete and steel (0.35% and 1%, respectively) with the elevation of temperature.
7. No additional deformation, cracking or any other manifestation will be taken into account for the calculation of reinforcement.
8. The effect of the thermal action on the shear strength of the reinforced concrete beams will not be considered. It is known that in normal situations, the force that takes these structural elements
to failure is the flexure. Therefore, the calculation of the reinforcement presented here will be only to combat this force.

The following items will describe in detail the thermal numerical modeling and the calculation of the reinforcement for the beam under study.

5. CASE STUDY

5.1. Thermal numerical modeling

ABAQUS adopts the principle of the conservation of energy to perform its thermal analysis. Regarding the method of analysis, the transient sort was adopted in this work, in which the thermal properties of the materials and the temperature distribution vary over time. The boundary conditions required to perform a thermal analysis refer to the three mechanisms of heat transfer: convection, radiation and conduction.

The convection and radiation are inserted in the model with the commands "Surface film condition" and "Surface radiation", respectively, which are available in the Interaction function of the computational code. The application of these phenomena occurs through the creation of a surface in the structural element and insertion of the quantities, the convection coefficient ($\alpha_c$) for the first mechanism, and the resulting emissivity of the material ($\varepsilon$) and Stefan-Boltzmann constant ($5.67 \times 10^{-8} \text{ W/m}^2 \text{ K}^4$) for the second. Regarding conduction, it is provided for the numerical analysis the density, specific heat and thermal conductivity for concrete and steel. The value adopted for the resultant emissivity of the concrete was 0.7, and for the convection coefficient, 25 W/m² °C.

The modeling was carried out based on the parameters and properties of the materials described in the Brazilian standard (NBR 1500, 2012) and European standard (EUROCODE 2 Part 1-2 (2004)) that deal with the behavior of reinforced concrete at high temperatures. The heating curve used to heat the structural element corresponds to the standard fire curve provided by ISO 834-1:1999. In this context, the thermal action with duration of 60 minutes was applied on the four faces of the beam with the objective of simulating a uniform heating.

This time corresponds to the minimum time that a beam, when present in a residential environment, must withstand fire, as provided in NBR 14432: 2000. With respect to the creation of the numerical model, the finite element of the solid type, DC3D8, was used to represent the concrete, and the bar element, DC1D2, for modeling the reinforcement. The insertion of the reinforcement in the concrete was done through the command *embedded region* that indicates to the computer code that they are positioned inside the concrete and both materials have perfect adherence. In the mesh generation, a refinement study was made, from which an automatic process was chosen which sought finite elements with a size equal to 30 mm.

It is important to note that in the computational codes, thermal numerical modeling is performed separately from the modeling in which the load of the structural element is considered. The analysis called thermo-structural, characterized by being the one in which a structural element is in a fire situation, is made by associating the results of each of the previously mentioned steps. Hence, naturally, in the numerical modeling performed in this article, which is the thermal analysis case, the possible effects caused by the load on the beam are not considered, so the reduction coefficients of the mechanical and thermal properties of the concrete and steel are not modified and correspond to those mentioned in the Brazilian and European standards. The thermal numerical results are described below.

5.1.1 Description of the thermal field

Using the parameters described above it was possible to obtain the thermal field formed in the cross section of the studied beam. In order to characterize the temperature advance along the section, six measurement points of this magnitude (T1 to T6) were selected and are indicated in Figure 5a that
presents the discretized beam. Based on this assumption, the evolution of the temperatures of these points is shown in Figure 5b.

As can be seen in Figure 5b, the reinforced concrete beam, even heated on all four sides, presented a non-uniform thermal field along the cross section, so that as it approached its geometric center, smaller the temperatures became. This is due to the low thermal conductivity of the concrete and the robustness of the section that promotes a differential heating of the structural element. The foregoing conclusion can be seen in Figure 6, in which the temperature variation developed in the section is illustrated for a time of 60 minutes exposure to fire.

It is important to emphasize that, as the numerical analysis was developed using the parameters (thermal properties and gas heating curve) provided by current fire standards, there will be no validation of these numerical models. This is because the experimental tests can hardly be calibrated by the normative parameters, since the heating curve usually obtained in tests differs from that of the standard fire. Moreover, since this is only a comparative study between types of reinforcement, the simplification above does not invalidate the purpose of this work.
5.2. Resistant capacity of the degraded beams

In the previous item, the reinforced concrete beam was modeled to represent its behavior in a fire situation. After obtaining the thermal field, it was possible to calculate the average temperature of the cross section that results in the reduction of the mechanical properties of steel and concrete. Prior to this calculation, as well as for the determination of the resistant capacity of the deteriorated element, a 1.5 cm thick layer of concrete was removed in every cross section for spalling representation, being the new section shown in Figure 7.

The average temperature for each section material, obtained in the thermal analysis, was 394.7ºC for the concrete and 358.5ºC for the steel. Based on the coefficients of the compressive strength reduction of the concrete (\(k_{c,\theta}\)), the yield stress (\(k_{s,\theta}\)) and the modulus of elasticity (\(k_{Es,\theta}\)) of the steel as a function of temperature described in NBR 15200: 2012 (Table 1) it was possible to reduce the mechanical properties of the materials.

To simplify the problem, the temperature of 400ºC in both materials will be considered to reduce the mechanical properties described above. In view of this, concrete is now considered with \(f_{ck} = 22.5\) MPa and steel, \(f_y = 470\) MPa and \(E_s = 147\) GPa.

Based on the calculation method presented by NBR 6118:2014, it can be concluded that the beam has lost 12% of its pure flexure resistant capacity, i.e., the degraded section will only withstand a requesting bending moment of 233.7 kNm which is now in deformation domain 3. As described in the initial hypothesis, the beam was subjected to a requesting bending moment of 265.7 kNm, it will need structural reinforcement.

5.3. Structural reinforcement design

In this item the necessary area of the structural reinforcement (carbon fiber and bonded-in steel sheet) is determined so that the degraded beam will again support the requested moment for which it was dimensioned. Therefore, initially the preexisting deformation in the steel ($\varepsilon_{\text{bi}}$), as a result of its initial loading, must be calculated as described in the reinforcement calculation methodology. Assuming that the permanent load corresponds to 80% of the total load acting on the beam and that it is a distributed single load, the requested moment of the calculation, due to this load, will correspond to 212.56 kNm. Thus, from the equilibrium equations and Hooke's Law, provided by the resistance of materials, it is calculated the deformation that the steel will have in the degraded beam which in this study was equivalent to 0.25%.

Following the methodology described in item 4, in the next items will be presented the calculation of the required area for the two types of reinforcements studied. In order to obtain the most economical situation in which the resistant moment ($M_{Rd}$) approaches the requested one ($M_{Rd}$), the position of the neutral axis was changed until it was reached the equilibrium equations.

5.3.1 Carbon fibers

The carbon fiber used in the development of this study corresponds to that provided by the company MasterBrace "BASF", it is called LAM 170/3100 "BASF", it has a square mesh of 120 mm wide, a thickness of 1.4 mm and a modulus of elasticity of 170 GPa. In Table 2, the design of the reinforcement with carbon fiber is shown in a simplified form.

In which,

$x$ - Position of the neutral axis;
$F_c$ - Concrete resistant force;
Contribution to the reinforced concrete beams degraded by fire: Comparative analysis between structural reinforcement with carbon fibers and steel sheets

Y. S. Simões, C. F. R. Santo

With the data presented in Table 2 it can be inferred that the position of the neutral axis, for an economic design associated with a correct balance of horizontal forces (resistant force of the concrete equal to the sum of steel and reinforcement resistant forces), is located between 19 and 20 cm. Analyzing this range of values, it is accepted that the value of \( x = 19.85 \) cm is the one that best meets the quoted criterion. For this value, the required reinforcement area is 1.35 cm² and the resistant moment is approximately 270 kNm.

As the carbon fiber has a width of 120 mm in each lamina and it has a thickness of 1.4 mm, only one layer of this reinforcement will be adopted along the whole span of the beam.

### 5.3.2 Bonded-in steel sheets

The laminated steel sheet used in this study corresponds to ASTM A 572 Grade 50, 4 mm thick, for structural works. According to NBR 8800:2008, sheet A 572, with a thickness of less than 100 mm and grade 50, has a yield stress of 345 MPa and a tensile stress equivalent to 450 MPa. Similar to item 5.3.1, Table 3 demonstrates the design for the bonded-in steel sheet.

<td>590.14</td>
<td>492.89</td>
<td>79.55</td>
<td>2.65</td>
<td>572.43</td>
</tr>
</tbody>
</table>

Based on the results presented in Table 3, it can be observed that the position of the neutral axis between 19 and 20 cm provides, in addition to a more economical design (\( M_{Rd} = M_{sd} \)), a better balance of horizontal forces. From the calculations, a value of \( x \) equal to 19.3 cm is defined. This value generates a resistant moment of approximately 265.8 kNm and a required area of reinforcement equal to 2.54 cm².

In view of this, it is adopted a steel sheet with the same width of the beam and a thickness of 1 mm to be distributed along the length of the structural element.

### 5.3.3 Comparative analysis between carbon fiber and bonded-in steel sheet

Analyzing the presented results, it is possible to verify that the use of bonded-in steel sheet, as structural reinforcement, requires a larger area for the degraded beam to recover its resistant capacity. This is justified by the high mechanical strength of the carbon fiber.
For practical purposes, choosing the best type of reinforcement involves a number of factors, such as price, useful section increase, performance, runtime, among others. In general, the literature points to carbon fiber as the best type of structural reinforcement because, although more expensive compared to steel sheets, it has a faster execution, better performance and does not significantly increase the cross section, in addition to being corrosion resistant.

In the case study presented in this article, the increase of the cross section was similar for both reinforcements due to the low request required for the performance of the carbon fiber and the steel sheet. In view of this, and based on the available literature, it is stated that when it is necessary the expressive increase of the resistant capacity of a beam associated with a low increase of the cross section, the use of carbon fiber tends to be more advantageous when compared to the steel sheets. However, as mentioned, the choice of the best type of reinforcement should be made in a judicious way, analyzing all the parameters that influence this decision.

6. CONCLUSION

It has been developed a study about the comparison between structural reinforcement with bonded-in steel sheets and carbon fibers applied in fire-damaged reinforced concrete beams. The cited pathology reduces the mechanical properties of the steel and concrete, so that the resistant capacity for which the structural element is designed decreases, which requires the application of reinforcement.

Therefore, a case study was developed in which a reinforced concrete beam was modeled using the ABAQUS computational code and exposed to standard fire on all four faces during an exposure time of 60 min. From the obtained thermal field, it was possible to determine the average temperature that the constituent materials were submitted, approximately 400°C, which was responsible for reducing its mechanical properties.

When calculating the necessary reinforcement for the beams, it was verified that the carbon fiber generated a smaller area in comparison to the bonded-in steel sheet, since the first one presents a high mechanical resistance. In general terms, it is recognised that the carbon fiber presents greater advantages with respect to the reinforcement of beams, such as speed in the execution and a not significant increase of the height of the cross section.

ABSTRACT

This work was aimed at analyzing the efficiency of the strengthening of reinforced concrete beams with the addition of steel bars and epoxy adhesive. Five beams were produced, out of which four beams were strengthened to flexure. In two of them, “U” clips were also used to improve the anchorage of the strengthening. The tests demonstrated that the clips reduced the resistances of the beams compared to those without clips. The strengthened beams without clips yielded better results, but the largest limiting factor was the adherence between the epoxy and beam. The use of clips for solving the problem of adherence made this research original. The conclusions were based on the comparisons of the tested beams.

Análisis experimental de vigas de hormigón armado reforzadas con barras de acero y adhesivo epoxi estructural

RESUMEN
Este trabajo tuvo como objetivo analizar la eficiencia del refuerzo en vigas de hormigón armado mediante la adición de barras de acero y adhesivo epoxi. Se produjeron cinco vigas. Cuatro recibieron refuerzo a flexión, y en dos de ellas fueron adicionadas también abrazaderas “U” para mejorar el anclaje del refuerzo. Los ensayos mostraron que las abrazaderas redujeron la resistencia de las vigas, en comparación con las que no tenían. Las vigas reforzadas sin abrazaderas obtuvieron mejores resultados, pero el factor limitante más importante fue la adherencia entre el epoxi y la viga. El uso de abrazaderas para intentar resolver el problema de la adherencia dio originalidad a esta investigación. Las conclusiones se basaron en la comparación entre las vigas ensayadas. Palabras clave: reforzamiento; viga; hormigón armado; encamisado.

Análise experimental de vigas de concreto armado reforçadas com barras de aço e adesivo estrutural epóxi

RESUMO
Esse trabalho objetivou analisar a eficiência do reforço com adição de barras de aço e adesivo epóxi em vigas de concreto armado. Foram produzidas cinco vigas. Quatro receberam reforço à flexão e em duas delas também foram utilizados grampos em “U” para melhorar a ancoragem do reforço. Os ensaios mostraram que os grampos reduziram a resistência das vigas em relação às sem grampos. As vigas reforçadas sem grampos obtiveram melhores resultados, sendo o maior limitador a adherência entre o epóxi e a viga. O uso dos grampos para tentar resolver o problema da aderência deram originalidade a essa pesquisa. As conclusões foram baseadas nas comparações entre as vigas ensaiadas. Palavras-chave: reforço; viga; concreto armado; encamisamento.

1. INTRODUCTION

The need to rehabilitate reinforced concrete structures by strengthening may arise because of the lack of maintenance during their lifespan and their adaptation to new uses when the option of demolishing and rebuilding them is not viable. In this case, some studies were conducted regarding the strengthening of reinforced concrete structures. However, because of the ongoing development in this topic of structural engineering, there is still no specific methodology for analyzing the structural behavior of the rehabilitated beams. According to Reis (Reis, 1998), intense studying in scientific research on the strengthening and rehabilitation of reinforced concrete structures is very important. This is mainly to define the designing rules better, understand the behavior of the strengthening of structures over time, and identifying approaches for analyzing the adhesion between the materials as well as their properties. These studies would enable determining which materials, techniques, procedures, and rules are more suitable to be used during the realization of structural rehabilitation. Therefore, the literature on the strengthening of reinforced concrete beams such as the papers by Helene (Helene, 2000), Cheong and MacAlevey (Cheong and MacAlevey, 2000), Reis (Reis, 2003), Alfaiate and Costa (Alfaiate and Costa, 2004), Altun (Altun, 2004), Santos (Santos, 2006), Lima (Lima, 2015), and Deghenhard et al. (Deghenhard et al., 2016) have been extremely important for the advancement of research in this area.
Although there are various strengthening techniques, this work will focus on the method of rehabilitation of reinforced concrete beams via the introduction of steel bars and epoxy structural adhesive (jacketing). The study of this technique, despite being antiquated, is still very important because of two simple reasons. First, it continues to be a widely used strengthening technique for small and medium works in Brazil. Second, in this research, serious problems were identified with this type of strengthening, which need further discussion. The main objective of this work was to study the rehabilitation of reinforced concrete beams by the addition of steel bars and epoxy structural adhesive.

2. EXPERIMENTAL PROGRAM

2.1 Characteristics of the beams
For this study, the Structure and Material Research Group (GEM) of Vale do Acaraú State University (UVA) produced five reinforced concrete beams, of which four were strengthened and one beam was used as a reference (not strengthened). All the beams were produced with the same dimensions: 80 cm length (with a span of 60 cm), 15 cm height, and 10 cm width, as shown in Figure 1.

The reference beam was not strengthened and is denoted as Beam E1. The other beams (E2, E3, E4, and E5) were strengthened by different approaches. All the beams had two longitudinal reinforcement bars with a diameter of 6.3 mm, and twelve transversal reinforcements (stirrups) with a diameter of 6.3 mm and 6.4 cm spacing. This arrangement of reinforcement bars was chosen so that the failure of the beams could be due to flexure. Figure 2 displays the details of the reinforcement of the five beams.
Beam E2 was strengthened to flexure with the insertion of two bars of $\phi$ 6.3 mm and 50 cm length in a “tooth” formed with epoxy adhesive (Figure 3).

Beam E3 was also strengthened to flexure with the insertion of two bars of $\phi$ 6.3 mm and 50 cm length in a “tooth” formed with epoxy adhesive. To improve the anchorage of the strengthening bars to the substrate of the beam, seven “U” shaped clips of 7 cm height and 4.5 cm width were inserted (see later in Figure 7), which penetrated 5.5 cm into the beam (Figure 4).

Beam E4 was strengthened to flexure with the insertion of two bars of $\phi$ 6.3 mm and 30 cm length in a “tooth” made with epoxy adhesive. The sizes of these bars were reduced to remain almost completely inside the pure flexure region (Figure 5).
Beam E5 was also strengthened to flexure with the insertion of two bars of $\phi$ 6.3 mm and 30 cm length in a “tooth” formed with epoxy adhesive. As in Beam E4, the sizes of these bars were reduced for them to remain practically completely inside the pure bending region (Figure 6). In Beam E5, to improve the anchorage of the strengthening bars to the substrate, four “U” shaped clips with 7 cm height and 4.5 cm width were inserted (according to Figure 7), which penetrated 5.5 cm into the beam (Figure 6).

![Figure 7. Details of the clip inserted in Beams E3 and E5 to assist in the anchorage between the strengthening and beam.](image)

The compressive ultimate strength of concrete ($f_c$) was obtained by an axial compression test of the cylindrical specimens on the same day of the tests of the beams, and it achieved an average resistance of 34.91 MPa. The tensile ultimate strength of concrete ($f_t$) was obtained by the indirect tensile test of cylindrical specimens (Brazilian test), on the same day of the tests of the beams, and it achieved an average resistance of 3.13 MPa. The tests for obtaining the compressive and tensile strengths of concrete were performed according to NBR 5739 (ABNT–NBR5739, 2007) and NBR 7222 (ABNT–NBR7222, 2011). Table 1 lists the characteristics of the tested beams.

Although the analyzed beams had reduced dimensions compared to real beams, it is necessary to emphasize that the aim of this work was not to determine any correlation between the reduced model and a prototype, through a dimensional analysis and laws of similarity, in a quantitative analysis. The aim was to only compare the structural behavior of the strengthened beams (E2, E3, E4, and E5) and reference beam (E1) in a qualitative analysis.

2.2 Test system
The beams built in this research underwent experimental tests performed at the Laboratory of Materials of Vale do Acaraú State University. They were submitted to the Stuttgart test, in which two concentrated forces equidistant from the supports were applied. This allowed studying the strengthening in the regions submitted to pure flexure and where shear effects (simple flexure) were also observed. Figure 8 illustrates a hydraulic press used for the tests.
The experimental tests are divided into two stages. In the first stage, beams E2, E3, E4, and E5 are subjected to a cracking load of 50 kN, which is equivalent to 60% to 80% of the failure load. The aim of this first stage was to crack the beams to simulate the need of strengthening. After removal of the 50 kN load, the beams were rehabilitated with steel bars and epoxy adhesive. The epoxy adhesive used to assist the anchor strengthening the bars to the substrate of the beam was Sikadur 31, which was not mixed with sand. The resistance to compression of Sikadur 31 at three days of age was 60 MPa, and the rehabilitation followed the manufacturer recommendations (Sika, 2015). One week after the rehabilitation, the second stage of the experimental tests began, which consisted of loading the beams through the Stuttgart test. The process was conducted with load steps of 10 kN until the beam exhibited failure. In each interval of the load applied to the beam, crack formation was examined and marked with a whiteboard marker to assist in the identification of the failure modes.

2.3 Computational model
The beams made for the experimental tests were also simulated in ANSYS software, which uses the finite element method for the discretization of structures. The computational modeling with the software was performed to replicate the conditions of the Stuttgart test performed in laboratory. Therefore, the same characteristics of the used materials were considered to obtain consistent results, which could then be correlated to the results of the experimental analysis. Figure 9 illustrates the modeling of the stirrups of Beam E1 and one of the other four beams, because of their identical rebars and spacing.

The supports and points of application of the loads were modeled with a 20 mm width, instead of 10 mm as in the tests, so that there were no stress concentrations in these regions, which could make the numerical convergence complex and cause an early failure.
To validate the results provided by the ANSYS software with the literature and study the effect of discretization on the precision of the results, the beams were modeled considering the individual properties of the steel and concrete materials: the modulus of elasticity, Poisson coefficient, and interactions between both the materials, as listed in Table 2.

Three-dimensional eight-node element Solid65 was used to model the concrete. This solid has three degrees of freedom in each node, and it is capable of cracking and crushing under tension and compression, respectively. This element considers the Willam–Warnke failure criterion for compression, and the tensioned region of the concrete is considered as an isotropic material with softening. The element is illustrated in Figure 10.
Three-dimensional element Link180 was used for modeling the reinforcements. This element has two nodes with three degrees of freedom in each node, and it is widely used to represent bars, trusses, and cables in a simplified way. This element only resists axial forces and assumes that the material exhibits the same behavior under compression and tension. An elastoplastic model is defined with a bilinear tension–strain graph as the failure criterion.

Shell element Shell181 was used to model the strengthening bars and epoxy adhesive. This type of element is mainly used for modeling jacketing with carbon fibers, but it can also be used for modeling external strengthening with steel bars. This element has four nodes with six degrees of freedom in each node and the capacity of plasticity, and its depth is considered in the analysis. The size of the mesh was 10 mm. According to Muliterno and Pravia (Muliterno and Pravia, 2016), in nonlinear analysis, the load is divided into a series of substeps so that in each substep the stiffness matrix is updated to consider the nonlinear alterations in the structural stiffness before going to the next substep. This analysis used 500 substeps, and in each load step, the load was applied from bottom to top and a force-based convergence criterion was used. The load was applied until a magnitude error occurred, which was considered as the moment of failure. The supports were inserted into the two superior faces of the elements of reaction and defined as zero displacements in the X, Y, and Z axes. The CEINTF command was executed to combine the nodes of the beam and reinforcement, considering that there was a perfect adherence between both the materials.

3. RESULTS AND DISCUSSIONS

3.1 Loads and Failure Modes

After a visual verification of the conditions of the beams after the failure, each tested beam was correlated to the computational model and compared to the reference beam. After all the beams achieved their ultimate load, a comparison was made between the rehabilitated and reference beams, analyzing the ultimate loads and failure modes. The most efficient strengthening method among the strengthened beams was also identified. Table 3 lists the details of the strengthening methods, ultimate load, and failure mode of each beam.

3.2 Effect of the Solicitation Mode

In the experimental tests, when the beams were subjected to the second stage, Beam E2 achieved an ultimate load of 108 kN, and it was verified that it failed after the strengthening unbonded from the beam, causing failure by flexure. Comparison with the reference Beam (E1) verified that its resistance increased by 35%.

The analysis of the results of the test of Beam E3 revealed that it failed after the strengthening unbonded from the substrate of the beam. However, unlike Beam E2, it had a different failure mode due to the compression of the strut. Comparison with the reference beam verified that the mechanical resistance of Beam E3 increased by 20%.

The analysis of the results of Beam E4 verified similar to Beams E2 and E3; it failed by flexure after the strengthening unbonded from the beam. Despite the indications of a compressed strut caused by the clips, the failure mode was flexural failure. It exhibited an increase of 45% in its resistance relative to the reference beam.

Beam E5 had the same failure mode as Beams E2 and E4; it was caused by flexure after the strengthening unbonded from the beam. Compared to the reference beam, its resistance decreased by 7.85%. Figure 11 shows the tested beams after their failure.

The results obtained through the ANSYS software verified that the ultimate loads yielded by the software agreed to the results achieved in the experimental tests. The failure modes of the beams and variation in the results compared to the reference beam were also similar. However, there was a difference in the strengthening: in the experimental test, the strengthening debonded from the beams before they underwent failure, but in the analysis, this did not occur because the friction between the beam and strengthening was not considered. Figure 12 presents the load–displacement plot of the five beams obtained from the computational analysis.
Dahmani, Khennane, and Kaci (Dahmani, Khennane, and Kaci, 2010) emphasized the symbology of ANSYS for the types of failure due to flexure (by flexural crack), shear (by shear crack), and compression (by crushing). These symbologies are presented as the labels in Figure 13. In addition, Dahmani, Khennane, and Kaci (2010) claimed that these symbols could also be combined depending on the type of failure. It is important to emphasize that this type of failure shown by ANSYS is a local failure, for example, the opening of a crack and a localized crushing. It alone does not provide the failure of the entire beam. A combination of these localized failures is what characterize the failure of the beam as a whole.

The aim of the numerical analysis of the strengthened beams was to show the stress distribution in the beams after the insertion of the strengthening, to provide results for comparison with the experimental results.

The analysis of the image, as generated by ANSYS (Figure 13), exhibiting the cracked beam the instant before it underwent failure as well as the location of the clips and strengthening. This verifies that in the region where the beam is strengthened, the appearance of compression stresses is very perceptible, mainly where the first clip is inserted in the beam (from left to right). From the correlation with the experimental test, it can be noted that this is the same region where concrete is crushed (Figure 11), i.e., the region where the beam undergoes failure.
The use of clips in the strengthening of the beams, which was aimed at improving the anchorage, generated concentrations of undesirable stresses in the beams. In the analysis of this problem using the Strut and Tie Model, a secondary strut from the top of the clip to the bottom of the stirrup was observed, which overloaded the existing strut (Figure 14).

Figure 13. Crack and crushing pattern generated by ANSYS for Beam E3.

Figure 14. Strut and tie Model for Beams E3 and E5.

4. CONCLUSIONS

In this work, the analysis of the results verified that the beams with clips assisted in the anchorage between the beam and strengthening (E3 and E5). More precisely, for Beam E3, the failure mode was a compressed strut, which could be reasoned by the increase in the field of compression of the beam caused by the addition of the clips. For Beam E5, which failed under a lower load than the reference beam (E1), it was verified that after perforating the beam to insert the clips, its stiffness was reduced, thus damaging the strength of the beam.

Beam E4 experienced the highest failure load, and it was only distinguishable from Beam E2, for which the same strengthening technique was used, through its length. It can be concluded that the strengthening of Beam E2 was effective in the region of simple flexure until it unbonded from the beam and underwent failure. The strengthening of Beam E4 was effective in the region of pure flexure, which explained its higher ultimate load in comparison to Beam E2 and all the other tested beams.

The aim of the computational analysis of the strengthened beams was to show the stress distribution in the beams after the insertion of the strengthening to compare them with the real results and validate them. Thus, it can be concluded that in general, the performed analysis satisfactorily simulated the experimental tests, explaining the failure due to the diagonal compression of Beam E3.
Analysis of the strengthened and reference beams revealed that Beams E2 and E4 were under superior ultimate loads compared to the other beams. However, it can be concluded that in this study, the addition of the clips to Beams E3 and E5 damaged their strength. Moreover, the unbonding of the strengthening, which occurred in all the strengthened beams, was because the epoxy resin has an elasticity modulus significantly lower than of the other materials of the system. Therefore, when a strengthened beam was loaded, because of insufficient stiffness, the resin did not transfer all the tension it received from the lower face of the beam. This resulted in the unbonding of the strengthening, indicating that only steel works. The scenario would be different if the materials had similar elasticity moduli. Thus, despite Beams E2, E3, and E4 having larger ultimate loads than the reference beam, the system does not operate efficiently. Therefore, it is not recommended to use this type of strengthening because it is ineffective and can be dangerous. It is important to emphasize that the conclusions of this work are limited only to the results of the tests of the five beams presented here. Other future research studies with more tests of beams and with and without strengthening are necessary for a better validation of this research.

ABSTRACT

The objective of this study is to evaluate the ultrasound test to estimate the depth of cracks in concrete, using a mathematical model published in the literature, and to verify this depth with more accurate results. Four concrete test specimens were molded for each proposed crack depth (5 cm, 10 cm, and 15 cm), simulated using zinc plates, placed during molding and removed before concrete hardening. The results show that the test is sensitive enough to detect the presence of the cracks in the concrete. The mathematical model used allowed for an estimation of the depths of most cracks, but the results are scattered and have a high margin of error for the depths of 5 cm and 15 cm. The cracks of 10-cm depth produced better results.

Evaluation of the ultrasound test for estimating the depth of cracks in concrete

1. INTRODUCTION

Cracks are the most common pathological manifestations found in concrete structures, usually appearing as a result of tensile stresses, which concrete has difficulty absorbing. Among the types of cracks that occur are those caused by thermal phenomena or by shrinkage (which are not structural hazards but may compromise sealing and performance), and those due to the lack of capacity of the structure to absorb tensile stresses, either by underestimation of the forces during sizing or by decrease of the material strength, the latter being of concern according to Silva Filho and Helene (2011). The timely detection of these defects can prevent rapid deterioration and prolong the useful life of the structures (Aggelis et al., 2010).

The evaluation of structures is usually performed through visual inspection, the results of which can be subjective because they depend on the experience of the inspector (Rocha and Póvoas, 2017). However, there are several non-destructive tests (NDTs) that allow for important information about concrete properties to be extracted (Rehman et al., 2016), and are usually used to locate and evaluate defects in hardened concrete (Lorenzi et al., 2016). Lee, Chai, and Lim (2016) consider that available methods for evaluating concrete cracks have their own limitations. The most commonly used NDT techniques for inspection of concrete structures are: ultrasound...
(Aggelis et al., 2010), thermography (Bagathiappan et al., 2013), pachymetry (Maran et al., 2015), radar (Dabous et al., 2017), and sclerometry (Tomazali and Helene, 2017).

The ultrasound test can determine the modulus of elasticity and specific mass of the concrete (Pacheco et al., 2014), estimate the compressive strength with a reasonably good approximation (Bungey, Millarde Grantham, 2006), and locate and determine the size of discontinuities in the structure (Menezes et al., 2016).

Several studies have been undertaken to detect cracks and fissures in concrete using the ultrasound test (Aggelis et al., 2010; Wolf, Pirskawetz, and Zang, 2015) and others to estimate their depth (Bungey, Millard, and Grantham, 2006; Pinto et al., 2010; Souza, 2016). The study developed by In et al. (2017) used the diffuse ultrasound technique to estimate the depth of cracks in concrete pieces that simulated real beams, performing a two-dimensional simulation of finite elements. This study concluded that it is possible to estimate the depth of cracks with deviations of 1 cm in relation to the real central measurement. Seher et al. (2013) also used diffuse ultrasound combined with two-dimensional finite element simulations, for which they analyzed the wave parameters to verify the variations between cracked and uncracked elements. It can be concluded that it is possible to estimate the depth of cracks with a maximum error of 10%.

It has been demonstrated in all of the studies that the results are influenced by several factors, such as: crack depth, concrete quality, and material saturation, among others. The objective of the present article is to evaluate the ability of ultrasound method to estimate the depth of cracks in concrete structures and specifically the influence of the depth of the cracks on the results, by analyzing the time variation of the sound wave through the cracked and uncracked areas.

2. ULTRASOUND TEST PROCEDURE

The ultrasound equipment used for concrete is designed to generate longitudinal waves, also known as sound waves (Bungey, Millard, and Grantham, 2006). Those whose frequency falls within the range of 20Hz to 20,000Hz are audible to the human ear, whereas the waves below 20Hz are called infrasonic and those above 20,000Hz are known as ultrasonic. (Possani et al., 2017).

The results obtained from the test may be affected by several factors, such as the distance between the contact surfaces of the transducers; the presence of reinforcement, especially if aligned in the direction of wave propagation; the specific concrete mass, which depends on the concrete mixture and conditions; the type, specific mass and other characteristics of the aggregate; the type of cement and degree of hydration; the densification type; and the age of the concrete (Pacheco et al., 2014, Lorenzi et al, 2013, Mohamad et al., 2015).

There are several advantages to using ultrasonic tests on concrete structures, such as: the tests are non-destructive, the equipment is cheap and easy to operate, and the test can be applied at any time, as it will not contribute to deterioration of the structure. However, the test does have some limitations, because the interpretation of its results is merely qualitative in relation to the quality of the concrete. It is therefore necessary to use it in conjunction with other tests in order to obtain more conclusive results (Aggelis et al., 2010).

Ultrasound tests in Brazil are regulated by NBR 8802 - Hardened concrete - Determination of the propagation of ultrasonic waves (ABNT, 2013). According to this standard, there are three ways for waves to be transmitted along the surface of the concrete: direct, semidirect, and indirect, as shown in Figure 1.
3. METHODOLOGY

To achieve the objectives of this study, concrete blocks were molded to represent real structural elements, in which cracks were induced to estimate depths using the mathematical model proposed by Bungey, Millard, and Grantham (2006). A total of 12 concrete blocks were molded, four for each of the three proposed crack depths (5 cm, 10 cm, and 15 cm). Four distances between the transducers were considered when performing the test (10 cm, 20 cm, 30 cm, and 40 cm).

To facilitate the analysis of the results, the blocks were divided into three groups (series) according to the crack depth: Series I - blocks with 5 cm deep cracks; Series II - blocks with 10 cm deep cracks; and Series III - blocks with 15 cm deep cracks.

The equipment used was the 58-E4800 UPV, with a standard frequency of 54 KHz using 50-mm diameter transducers (CONTROLS GROUP, 2017).

3.1 Test specimens

The concrete blocks had dimensions of 20 x 20 x 50 cm. The crack was induced along the axis of the block by placing a 0.95 mm thick zinc plate during the molding, which was then removed before the concrete hardened. All of the blocks were produced with the same depth, because research in the literature showed no influence on the results caused by the depth. Figure 2 shows the details of these test specimens.
The water/cement ratio used was 0.5 and the mixture (cement:gravel:sand) was 1:1.46:2.51. The cement used was CPII Z-32. The gravel and sand were tested according to standard NBR 7211 (ABNT, 2009), where the granulometric distribution met the recommended limits and the maximum diameter of the gravel was 19 mm.

In order for the number of blocks used in the study to be statistically representative for the analysis of results, it is important that the observations of the independent variables are in a proportion greater than 5 to 1, that is, more than 5 observations for each independent variable. The recommended level is between 15 and 20 observations per variable, so that the sample can be considered representative (Hair et al., 2009). This study analyzed two independent variables, crack depth and test execution distance. When multiplied by 20, this gives an ideal quantity of 40 observations. In total, 96 observations were performed (4 blocks x 3 depths x 4 distances x 2 repetitions), a value well above the recommended amount.

3.2 Mathematical model for estimating crack depth proposed by Bungey, Millard, and Grantham (2006)

The model allows for the estimation of crack depth perpendicular to the concrete surface when the mode of transmission is indirect. Therefore, the transducers should be placed equidistant from the crack, as shown in Figure 3 (a) and (b).

In order to apply this model, the velocity of the ultrasonic wave through the integral concrete obtained using the indirect mode should be adopted as "Vc". That is, a speed "Vc" is found in a region of the concrete without cracks, having a distance of \( Y = 2X \) between the transducers. Considering that the wave will deviate around the crack and that the velocity should remain the same because it is propagating through similar material, it is possible to estimate the depth of a
crack that has its axis located at distance "X" from the transducers, as shown in Figure 3. The difference between these two paths will cause a slower wave propagation time, because the speed "Vc" should be the same.

The model assumes that the velocity will be equal for the two paths and that the wave will deviate because it is a mechanical wave, which requires a medium through which to propagate. Equation (1) represents the proposed mathematical model, a result of the equality of velocities along the two wave paths.

\[
h = x \sqrt{\frac{T_f^2}{T_c^2} - 1} \text{ (cm)}
\]

Where:
- \( h \) = crack depth estimated by the model (cm);
- \( x \) = distance from the transducer to the axis of the crack (cm);
- \( T_c \) = wave propagation time through unbroken whole concrete, defined as (2).

\[
T_c = \frac{2x}{V_c} \text{ (\( \mu s \))}
\]

\( T_f \) = wave propagation time around the crack, defined as (3).

\[
T_f = \frac{2\sqrt{x^2 + h^2}}{V_c} \text{ (\( \mu s \))}
\]

### 3.3 Test execution

The ultrasound test was performed using the indirect mode, avoiding roughness on the tested surface as indicated by NM-58 (ABNT, 1996). The calibration of the equipment was performed before beginning the measurements, according to the procedure described in the manual (CONTROLS GROUP, 2017).

An observations grid was marked on the surface used for the test, composed of an upper and lower line, the detail of which is shown in Figure 4. At all points where measurements were to be taken, Vaseline was applied to connect the transducer to the surface.

At each grid point, two readings were performed using the ultrasound and their average was used for the calculations of the model. Standard NBR 8802 (ABNT, 2013) provides guidelines for obtaining the velocity of wave using the indirect mode, where the emitting transducer is at a fixed point and the receiving transducer is shifted at predetermined distances. With the data obtained, a time versus distance graph can be plotted to draw the line that best fits the points, with the tangent of the line being the wave velocity.
In order to apply the Bungey, Millard, and Grantham (2006) model, it is necessary to obtain the propagation time of the wave using the indirect mode in intact concrete - Tc, which must be obtained for the same distances that are to be measured in the cracked region - Tf.

To obtain Tc, the emitting transducer was fixed at the first point of the mesh and the receiving transducer was moved in 5-cm steps, obtaining times for the distances Y = 5cm, 10cm, and 15cm, according to Figure 5 (a), (b), and (c), where E is the transmitter, R is receiver, and Y is the distance between transducers (cm).

The results of the three readings of distance (cm) versus time (μs) were plotted to obtain the best fit line (Figure 6) and to find the propagation times through intact concrete, adjusted by the line Tc’ for all distances required to apply the model: Y = 10cm, 20cm, 30cm, and 40cm, as shown in Table 1, which presents the results of the first repetition for the first test specimen of Series II. The measurements are identified first by the number of the block in the series (1, 2, 3, or 4), then by the depth (P5 = 5cm, P10 = 10 cm, P15 = 15 cm), followed by the test execution distance D10 = 10 cm, D20 = 20 cm, D30 = 30 cm, D40 = 40 cm) and finally by a unique number for each repetition of the test (1 for the first and 2 for the second).

Linear Equation

$Y = 0.3328X - 2.4862$

$Y$-intercept -2.4862

$"V_c"$(cm/μs) - Angular coef. 0.3328

The adjusted times ($T_c'$) were found for the distances $Y = 10\text{cm}$, $20\text{cm}$, $30\text{cm}$, and $40\text{cm}$, where $Y = 2X$, with $X$ being the distance between the axis of the crack and the transducer.

In order to measure the propagation time of the wave around the crack ($T_f$), the readings were taken with distances between the transducers of $Y = 10\text{cm}$, $20\text{cm}$, $30\text{cm}$, and $40\text{cm}$, as shown in Figure 7 (a) (b) (c) (d).

Once the values for $T_c'$ and $T_f$ have been obtained for the same distances, it is possible to estimate the depth of the crack using the model proposed by Bungey, Millard, and Grantham (2006), following the procedure presented in the previous section.

The procedure shown for obtaining the $T_c'$ and $T_f$ values was repeated two times for each of the four concrete blocks per series, for all three series.

![Figure 7. Readings taken around the crack with transducers at distances of: (a) 10 cm; (b) 20 cm; (c) 30 cm; (d) 40 cm](image-url)
4. ANALYSIS AND DISCUSSION OF RESULTS

A statistical analysis was performed with the results for the crack depths (h') for Series I, II, and III found by the application of the mathematical model proposed by Bungey, Millard, and Grantham (2006), in order to verify which series presented the most significant results.

Table 2. summarizes the results for Series I, II, and III.

* Results that could not be calculated by the model, because Tc > Tf.

Table 2 shows that the mathematical model of Bungey, Millard, and Grantham (2006) could be applied to calculate the depth of cracks in 88.5% of observations. For the remaining percentage,
Evaluation of the ultrasound test for estimating the depth of cracks in concrete

11.5%, it was not possible to determine the depth because the wave propagation time in the cracked region was less than the time in the uncracked region, making the model impossible to apply. Analysis of the results from the series using the descriptive statistics are presented in Table 3.

It can be seen from the results that the model presented significant variation for all three series. Series III (15 cm) presented the highest variance and standard deviation in comparison to the other series, showing a high level of dispersion in the data set. Series II (10 cm) had the best indices in the analysis of the dispersion of the data, presenting smaller variance, standard deviation, and coefficient of variation. Series I (5 cm) had an intermediate level of dispersion, but the coefficient of variation was higher, as the standard deviation represented about 55% of the mean.

Pinto et al. (2010) also studied the estimated depth of cracks in concrete blocks, analyzing four different depths (50 mm, 75 mm, 100 mm and 150 mm), with test execution distances of 100 mm and 150 mm, applying the same mathematical model and arrived at the estimates presented in Figure 8, where the tests were identified by the series, then the depth, and then by the test specimen analyzed. For example, S1-75-B indicated Series 1, depth 75 mm, block B.

Figure 8. Crack depths (Pinto et al, 2010)
The authors concluded that the results were mostly within the margin of error of 15% of the actual crack depth. A similar result occurred in this study, where the best results were found for crack depths of 10 cm.

To facilitate the understanding of the behavior of the results found, the boxplot of the three series was used in Figure 9, a graphical statistical tool that represents the variation of the data of a numerical variable through quartiles.

A boxplot is formed by drawing a box parallel to the axis of the variable. The lower edge represents the 1st quartile, the thick line the median (2nd quartile), and the upper edge the 3rd quartile. The line that extends vertically indicates the upper and lower limit of the data. This box represents 50% of the central values of the distribution. The flatter the box, the less scattered the data is.

It can be seen that the data from Series II (10 cm) were those with least variability, as data from Series III (15 cm) had greater dispersion. It can be said that the data from Series II (10 cm) behaved better in comparison to the other series in the analysis of descriptive statistics.

To complement the analysis, inferential statistics were used, with the application of a confidence interval (CI) of 95%. This refers to a numeric interval around the mean that will contain 95% of the values, on average. The CI value represents, more or less, a margin of error in relation to the mean.

For this study, a 20% margin of error was considered acceptable. Using the actual crack depth measurement as a reference, this implies margins of error of 1 cm for Series I, 2 cm for Series II, and 3 cm for Series III.

Table 4 shows the confidence intervals of the depth variable for the 3 series analyzed. Figure 10 shows the graphs of the confidence intervals for each series with regard to depth.
Corroborating what was determined in the descriptive analysis, the data from Series III (15 cm) had a higher value for the C.I. than the other series, while Series II (10 cm) had the smallest C.I. A greater C.I. means that the margin of error that ensures 95% confidence increases, making the interval larger, which can be seen in Table 4.

With too large a range, meaning a high margin of error, the application of this procedure on real structures becomes impractical, as it will lead to a great variation in the estimate of the depth of the cracks.

For Series III, the depth variation calculated by the model falls within the range of 13.14 cm to 17.57 cm, with the actual depth being 15 cm.

In Series II, which had the smallest C.I., the depth calculated by the model varies from 6.48 cm to 8.14 cm. Although this is a small interval, the actual depth measurement of 10 cm does not fall within it, a fact that compromises the application of the model.

For Series I, which had an intermediate C.I., with crack depths calculated by the model ranging from 5.51 cm to 8.40 cm, the actual depth of 5 cm also lies outside the range.

It is also possible to see from the results that, for larger distances between the transducers (30 and 40 cm), there is a greater variation of the data, whereas the smaller test execution distances (10 and 20 cm) had less dispersion and a smaller margin of error.

It is possible to apply the proposed model and determine the depths of cracks, but with a high degree of dispersion in the results. This high variability is mainly due to concrete that is not homogeneous, where the wave propagation velocity can vary. It is also possible that the propagation path of the wave may differ from the ideal path considered by the model.

5. FINAL CONSIDERATIONS

In the current study, an experiment was carried out to statistically evaluate the efficiency of the ultrasound method for the estimation of crack depth. The test provides clear information on crack detection in concrete, since the wave propagation time is considerably longer than that in areas of intact concrete.
The estimation of crack depth using the model proposed in the literature made it possible to find values for a large percentage of the observations made. However, the values are widely dispersed, and have a high margin of error, compromising the results and the ability to apply the model in the field.

Combining this test with other nondestructive tests may provide better characterization of these defects and more information, in this way eliminating some of the uncertainties presented by the ultrasound method alone.

ABSTRACT

This paper presents an experimental program to determine the residual strength of simple supported reinforced concrete beams subject to bending after fire. Also presented is a three-dimensional, nonlinear finite element model capable of predicting the thermal and mechanical (residual) behavior of this type of structural element. The experimental results obtained with beams under up to 120 min. of fire exposure show that it did not have significant reduction in their residual resistance. The numerical model was accurate in predicting temperatures and residual strength when compared to the experimental results.

Keywords: beam; reinforced concrete; residual strength; after fire; experimental and numerical analysis.

Assess of residual mechanical resistance of reinforced concrete beams after fire

R. G. Pereira, T. A. Carvalho Pires, D. Duarte, J. J. Rêgo Silva

1. INTRODUCTION

Due to the Brazilian urbanization, the concern with fire safety in buildings in Brazil has increased. More than this, it becomes increasingly common for engineers and architects to have their services required to assess and recover structures in buildings after fires. In order to get an idea of this market, the Metropolitan Region of Recife, capital of the state of Pernambuco, Brazil, with 4,046,845 inhabitants, registered an average of 1,634 fires per year in buildings (most of them being residential buildings), according to Corrêa et. al. (2015). This number draws attention from the local technical community to the need to deepen the understanding of the structural behavior of buildings in a fire situation, during its cooling and after the fire.

Advantages of reinforced concrete in fire situation are already mentioned in the literature, for example: being non-combustible, not exhaling toxic gases, not having (usually) thin sections and having low thermal conductivity, delaying the increase of temperature into the interior of the piece and, consequently, minimizing the damage caused by the fire with respect to reduction of the mechanical properties of constituent materials.

Neville (1997) confirms this good performance of the concrete regarding fire resistance, i.e., the time of fire exposure with satisfactory performance is relatively large and there is no release of
toxic gases. Satisfactory performance is understood as the ability to withstand loads, flame penetration resistance and heat transfer resistance.

However, it is also known that the high temperatures reached in the fire cause physical and chemical phenomena that result in the reduction of mechanical properties, that is, in the compressive strength, tensile and modulus of elasticity, of the constituent materials (steel and concrete), besides (spalling) phenomenon that can compromise the structural element's resilient capacity (PIRES, 2007).

Among the causes that can lead to a structure subject to high temperatures to collapse, Morales (2011) highlights the maximum temperature reached, the exposure time, the concrete trace, the type of structure, the structural element and the cooling velocity.

After the fire and the cooling of the structure to reach room temperature, the residual strength of the concrete structure is the main parameter to assess the level of damage and the safety of the structure, having a considerable influence on the structural recovery work (GUO AND SHI, 2011).

Silva (2012), also emphasizes that the value of resistance after cooling depends on the temperature reached during the fire and the cooling rate, the faster the cooling, the more damaging it will be for the concrete’s resistance.

Experimental research, such as those conducted by Guo and Shi (2011) and Maraveas et. al. (2017), respectively, determined the reduction of residual mechanical properties of concrete and steel after heating to temperature levels. Figure 1 summarizes these results.

![Figure 1. Reduction factors for the residual compressive strength of concrete and for the flow of steel after cooling.](image_url)

The elevation of the temperature in the steel causes reduction in its resistance. After cooling, steel may, under certain circumstances, recover its initial strength. Transformations in its crystallography, obtained at temperatures above the eutectic point (approximately 720 ° C), partially impede the recovery of the resistance, thus, there is a residual loss of resistance (Smith et al., 1981, apud SILVA et al., 2006). This reduction factor is presented in Figure 1. However, it is worth noting that the international literature presents several values for the reduction of the mechanical properties of the materials after fire and often with very divergent values. This demonstrates the need for more research to reach consensus.
This work aims to simulate experimentally the impact caused by a fire in reinforced concrete beams. Then, a numerical model developed in the ABAQUS finite element program will be presented in order to evaluate the residual mechanical strength of these beams. In this sense, it is expected to contribute to the procedure for evaluating reinforced concrete structures after fires, presenting a valid strategy for this purpose.

2. EXPERIMENTAL MODEL

The experimental program developed in this research was carried out at the Structural and Materials Laboratory of the Civil Engineering Department of the Federal University of Pernambuco and the Francisco Adriissi Ximenes Aguiar Technical School (SENAI - FAXA), in the municipality of Cabo de Santo Agostinho - PE.

In the experimental program, 12 reinforced concrete beams with a length of 1.20 m and cross section of 0.12 m x 0.20 m, representing the base and the height respectively, were tested. The compressive strength of the concrete after 60 days is fc = 47.6 MPa and was determined, by arithmetic mean, through 4 cylindrical specimens measuring 0.10 m x 0.20 m. The concrete was dosed and had the characteristics shown in Table 1.

For positive longitudinal reinforcement, two bars $\phi = 10$ mm, CA-50 steel, were employed and for transverse reinforcement, bars of $\phi t = 6.3$ mm, CA-60 steel were used, with spacing close to the supports of 60 mm and 80 mm in the central region of the beam. In the upper part of the beam, 2 bars $\phi m = 6.3$ mm, Steel CA-60, were used as mounting reinforcement, only with the stirrup holder function. The concrete cover c1 (distance between the face and the longitudinal reinforcement axis), according to NBR 15200:2012, was 30 mm.

The assay was performed after 60 days of sample curing and consists of two steps. First, the heating of the beams, according to the curve of Figure 2. In this step, there is no application of mechanical load. Then, after 24 hours, time for the cooling, the mechanical load was applied until the rupture, according to the model of Figure 4 (c).

Three beams were tested at room temperature, that is, without heating to determine the reduction of residual resistance.
The heating of the beams, without application of mechanical load, took place in three batteries of fire tests with durations of 60 min., 120 min. and 210 min., corresponding to the programmable limits of the furnace used, with three samples (beams) for each battery. The heating curve is shown in Figure 2.

Due to the limitation of the furnace employed, the standard fire curve (NBR 15200:2012) could not be adopted. For comparison purposes, this curve is also represented in Figure 2.

![Temperature of the gases inside the furnace during heating for all experiments](image)

In table 2 the characteristics of the furnace used for fire exposition of the beams at elevated temperatures are presented. Figure 3 shows the photo of this furnace.

The beams were exposed to fire in 3 faces, considering the worst situation in a fire situation. The compressed face of the beam was insulated with the ceramic fiber blanket (insulation material).
inside the furnace, as shown in Figure 4 (b), to ensure that the top of the beam was not heated by conduction. The temperatures inside the structural part and the gases inside the furnace were monitored by 20 K-type thermocouples: 16 of them were placed along the beam, as shown in Figure 5, and 4 thermocouples located on the top of the furnace.

The mechanical test of the beams occurred after cooling to room temperature. The load was applied by a hydraulic press whose maximum load capacity was 3000 kN, according to Figure 6. Throughout the mechanical test the mechanical load applied to the beam was recorded by 300 kN load cells. The test scheme is shown in Figure 4 (c) where the beams were loaded until rupture. The load application rate was 1 kN /s.
3. NUMERICAL MODEL

3.1 Geometric Properties of Beams
In this work, the three-dimensional, non-linear numerical model for finite element analysis of reinforced concrete beams was developed in the ABAQUS / Standard program (2013). The geometric properties of the model follow strictly what is described in the experimental program.

3.2 Type of Finite Element
The ABAQUS library has a variety of finite elements of different types such as Solids, Shell, Membrane, Frame, among others. In this study, in the thermal analysis, two types of finite elements were used for discretization of the respective beams, being:
- DC3D8, being the same 3D, of linear formation and composed of 8 nodes, for concrete and longitudinal reinforcement;
- DC1D2, element 1D, that is, link, with linear formation and composed of 2 nodes, used in the transverse reinforcement.

For mechanical analysis, the following elements were adopted:
- C3D20R, solid type element, used in the discretization of the concrete. It is a continuous element (C), three-dimensional (3D), with twenty nodes (20), reduced integration and has the option *hourglass control*, which allows to improve the resolution of problems related to obtaining oscillatory solutions, exhibiting spurious modes, that is, when the matrix becomes singular or almost singular (when the matrix does not admit inverse). It presents quadratic formation and three degrees of freedom of translation at each node;
- C3D6, a solid type element used in the discretization of the longitudinal reinforcement. It is a continuous element (C), three-dimensional (3D) and with six nodes (6).
- T3D2, lattice element that has two nodes, presenting three degrees of freedom per node, referring to the translations in the x, y and z directions. This element was used in the discretization of the transverse reinforcement.

Figure 7 illustrates the types of elements used in the numerical model.

![Figure 7. Two-node finite element, six-node prismatic triangular finite element, eight-node hexahedron finite element, twenty-node hexahedron finite element, respectively. (RODRIGUES et al. (2016))](image)

3.3 Finite Element Mesh
The reinforced concrete beams were discretized in the thermal analysis in elements of 10 mm x 10 mm x 10 mm for concrete, 20 mm x 20 mm x 20 mm for longitudinal reinforcement and 20 mm for transverse reinforcement. For mechanical analysis, meshes of 50 mm x 50 mm x 50 mm for the
concrete, 40 mm x 40 mm x 40 mm for the longitudinal reinforcement and 20 mm for the transverse reinforcement were discretized.

For each analysis, thermal and mechanical, approximately 49066 and 2514 elements were generated, connected by 56808 and 9907 nodes, respectively. It was verified that there would be no significant improvement in the results with more refined meshes.

3.4 Properties of Materials

For the numerical analysis, thermal and mechanical properties for the materials of reinforced concrete beams were adopted according to national standards NBR 6118 (2014), NBR15200 (2012) and NBR14323 (2013).

For thermal analysis it is necessary to define the specific mass, coefficient of thermal expansion, thermal conductivity and specific heat for concrete and steel as a function of temperature. The specific mass was considered constant, with values equal to 7850 kg/m³ and 2400 kg/m³ for steel and concrete, respectively.

For mechanical analysis it is necessary to define the modulus of elasticity, Poisson coefficient and the plastic properties of the materials as a function of temperature.

When it is considered that the structure will undergo finite deformations, the tensions (σ) and deformations (ε) must be considered based on the actual geometry of the deformed structure. The true values are given by equations (1) and (2).

\[
\varepsilon = \ln(\varepsilon_{nom} + 1) \quad (1)
\]

\[
\sigma = \sigma_{nom}(\varepsilon_{nom} + 1) \quad (2)
\]

In ABAQUS the plastic behavior of the material defined by these measurements is considered, with the true tension related to the plastic part of the true deformation (SILVA, 2006).

The mechanical properties of the materials at room temperature were obtained through experimental tests: compressive strength of 47.6 MPa for the concrete; and flow stresses of 500 MPa and 600 MPa for the steel used in longitudinal bars and transverse bars reinforcements, respectively. The modulus of elasticity adopted for the steel was 210 GPa.

In order to determine the residual value of the mechanical properties, the coefficients proposed by Guo and Shi (2011) and Maraveas et al. (2017), respectively, for concrete and steel, since these values are commonly employed in similar studies.

The Poisson coefficient can also be considered constant, and so the values adopted were 0.3 and 0.2, respectively, for steel and concrete.

3.5 Contour Conditions, Loading and Contact.

To simulate the thermal action in the numerical model, two types of surfaces, around the beam subjected to high temperatures, were used, namely, film condition and radiation, which represent, respectively, the phenomena of heat transfer by convection and radiation. It should also be noted that the value of 0.95 for the emissivity of the concrete was considered. The value of 25 W/m² was adopted for the heat transfer coefficient by convection.

For the thermal analysis, the contact between concrete and longitudinal and transverse reinforcements were modeled with Tie behavior, simulating the perfect contact, so that there was no loss of heat.
In the mechanical model, the contact between the concrete and the reinforcements was made by the *Embedded region* function, in order to guarantee a perfect solidarity between the materials, according to the fundamental hypothesis of the reinforced concrete theory. The numerical model represented bi-supported condition for the beams used in experiments, with span of 1.20m (Figure 8).

Following the experiment, two equal concentrated loads were applied to the upper face of the beam, equidistant from the middle of the span, that is, 0.35 m, with a velocity of 1 kN /s, according to Figure 4 (c). The auxiliary command *constraint coupling*, located in the *interaction* menu in ABAQUS, which has the function of avoiding the concentration of efforts at the point of application of the concentrated load, was also used. In addition to these loads the weight of the beam was also considered.

Finally, it is emphasized that the geometric nonlinearity parameter was activated (* NLGEOM = ON*), so that the effect of large displacements was considered.

**4. NUMERICAL AND EXPERIMENTAL RESULTS**

**4.1 Temperature analysis**

In this section, the temperatures results of the concrete beam recorded during the experiments and those obtained from the numerical model are compared. Figures 9, 10 and 11 (a) shows these results at the beam cross section. The point chosen for comparison is shown in Figures 9, 10 and 11 (b), in red. At this point thermocouples were positioned in the experiment, facilitating this comparison. The temperature gradient in the concrete section is obtained through the numerical results and is represented in the same Figures 9, 10 e 11 (b).
In the three test batteries, i.e. 60 min., 120 min. and 210 min, the experimental and numerical temperatures for the concrete presented very close values, evidencing a strong correlation between these results (Figures 9, 10 and 11). Some divergence is observed for temperatures around 100°C. This difference can be attributed to the movement of water vapor inside the concrete and not faithfully represented in this numerical model. For this, it is necessary to develop a thermo-hydraulic-mechanical model for this analysis.

Figure 9. Evolution of temperatures in concrete, num. x exp., in the test of 60min (a) and temperature gradient in the cross section, in the middle of the span, at time t = 60min (b).

Figure 10. Evolution of temperatures in the concrete, num. x exp., in the test of 120min (a) and temperature gradient in the cross section, in the middle of the span, at time t = 120min (b).
It is evident the low conductivity of the concrete generating high temperature gradients (Figures 9, 10 and 11). This gradient may contribute to the occurrence of spalling, specially at the corners of the cross section. However, in the experimental test there was no spalling, probably because it was a concrete not dense enough (fc = 47.6 MPa) and low humidity (4.4%).

On the other hand, the low conductivity of the concrete slows down the temperature increase in the region of the steel bars and the inner core of the concrete, allowing it to retain its resistance, and consequently, to perform better in the fire.

It is noteworthy that near 100 °C, temperature growth curves presented a short period of time (around 10 minutes) without significant increase. This is a result of the change of state of free water existing in the parts. This phenomenon was also observed in specimens from previous experiments, as reported by Kalifa et al. (2000). As previously mentioned, in this section the numerical model does not faithfully follow this behavior, but nevertheless, it presents an acceptable approximation of the results, i.e., maximum difference lower than 50 °C.

Thus, it can be concluded that the numerical model was able to represent the temperature distribution in the reinforced concrete beams with results very close to those recorded experimentally.

4.2 Mechanical analysis

This section presents the value of residual strength after cooling of the concrete beams tested, as well as this value obtained by the numerical analysis.

In order to allow the comparison between the loads obtained numerically and experimentally, the value of the vertical displacement in the middle of the span (arrow) for the maximum load supported by the beam was adopted as failure criterion. This value was defined according to the expression recommended by NBR 6118 (2014) for cracked concrete structures as a function of the load of rupture applied to the beam.

Table 3 presents the comparison of the load of rupture of the reinforced concrete beams obtained in the experimental program and through the numerical model.
Table 3. Experimental and numerical load limits

</tbody>
</table>

The times of 60 min and 120 min of fire exposure were not sufficient to significantly reduce the residual strength of the reinforced concrete beam. It is observed that the temperatures developed in the section were not high enough to cause a degradation of the constituent materials up to 120 min of fire exposure. This shows the good performance of the reinforced concrete structures when subjected to fires. However, the heating of 210 min caused a considerable reduction in the residual resistance; the load of rupture in this situation was of 47.6 kN, that means, 60% of the maximum load capacity at ambient temperature (Table 3).

Finally, it was observed that all numerical results had a very similar tendency to those obtained experimentally, with errors less than 7% in determining the load of rupture of the beams of reinforced concrete. In this way the model is valid and accurate enough to predict the residual structural behavior of reinforced concrete beams submitted to pure bending after fire.

5. CONCLUSIONS

This work presented an experimental program to determine the residual strength of reinforced concrete beams after a fire. In addition, a numerical, non-linear numerical model developed in finite elements capable of simulating the thermal and mechanical behavior of this type of structural element was presented. Based on these results the following can be highlighted:

- The reinforced concrete beams presented a good residual performance after fire, resisting to 120 min without loss of resistance;
- The numerical approach developed for thermal analysis produced quite satisfactory results when compared with those obtained experimentally;
- The numerical approach developed for residual mechanical analysis produced accurate results with errors lower than 7% when compared to the experiment;
- The numerical model presented can be used to predict the thermal and mechanical (residual) behavior of reinforced concrete beams bi-supported after the fire;

ABSTRACT
This paper presents the results of concretes manufactured with supersulfated cement (SSC) based on volcanic materials. The concretes were cured under two regimes, one for 24 h at 25 °C and another for 22 h at 60 °C and then at 25 °C. The specimens were exposed to two conditions: dry laboratory conditions and immersed in a solution with 3.5% CaSO4 at 25 °C for up to 180 days. After 180 days, the concrete with a cementitious compound of 5%An-10%PC-10%CaO-75%PM reached a compressive strength of 46 MPa exposed to CaSO4 solution and of 44 MPa in dry laboratory conditions. The microstructure was analyzed by scanning electron microscopy, energy-dispersive X-ray spectroscopy and X-ray diffraction, which showed that the main hydration products are C-S-H and ettringite.

Keywords: supersulfated concrete; pumice; compressive strength; sulfate environment.

Resistencia a la compresión y microestructura de concretos fabricados con cementos supersulfatados base materiales de origen volcánico expuestos a un ambiente de sulfato

RESUMEN
Esta investigación presenta los resultados de concretos fabricados con cementos supersulfatados (SSC) bases materiales volcánicos. Los concretos fueron curados bajo dos regímenes uno por 24 h a 25°C y otro por 22 h a 60°C y luego a 25 °C. Los especímenes fueron expuestos a dos condiciones, en seco en condiciones de laboratorio e inmersos en una solución con 3.5% CaSO4 a 25°C hasta por 180 días. Después de 180 días, el concreto con un cementante compuesto de 5% An-10%PC-10%CaO-75%PM expuesto a la solución de CaSO4 alcanzó una resistencia a la compresión de 46 MPa y 44 MPa en seco en condiciones de laboratorio. La microestructura fue analizada por microscopía electrónica de barrido, espectroscopia por dispersión de energía y DRX, mostró que los principales productos de hidratación son C-S-H y ettringita.

Resistência à compressão e microestrutura de concreto fabricado com materiais à base de cimento supersulfatado de origem vulcânica expostos a um ambiente de sulfato

RESUMO
Esta pesquisa apresenta os resultados de concretos fabricados com cimentos supersulfatados (SSC) com bases de materiais vulcânicos. Os concretos foram curados sob duas condições, uma por 24 h a 25°C e outra por 22 h a 60°C e depois a 25°C. As amostras foram expostas a duas condições, a seco em condições de laboratório e imersas em solução com 3,5% de CaSO4 a 25°C por até 180 dias. Após 180 dias, o concreto com um cimento composto de 5% An-10% PC-10% CaO-75% PM exposto à solução de CaSO4 atingiu uma resistência à compressão de 46 MPa e 44 MPa em condições secas de laboratório. A microestrutura foi analisada por microscopia eletrônica de varredura, espectroscopia de dispersão de energia e DRX, mostrando que os principais produtos de hidratação são C-S-H e ettringita.

Palavras-chave: concreto supersulfatado; pedra-pomes; resistência à compressão; ambiente de sulfato.

1. INTRODUCTION
Concrete is the most widely used composite material in the world, which implies that Portland cement (PC) is the construction material with the highest consumption and production, with an annual production of almost 2 billion tonnes, emitting approximately 2 billion tonnes of CO2 (Shi et al., 2011). The effort to reduce air pollution has led to the development and use of new environmentally friendly cementitious materials, such as supersulfated cements (SSC), due to their energy savings, low carbon emissions, and reuse of waste (Ding et al., 2014). These cements can reduce CO2 emissions up to 90% compared to PC (Woltron, 2009). The SSCs are commonly composed of granulated blast furnace slag, a sulfate source such as hemihydrate (HH) or anhydrite (An), and a small amount of alkaline activator, mainly clinker and PC (Kühl, 1908; Midgley and Pettifer, 1971; Bijen and Niël, 1981; Mehratra et al., 1982; Dutta and Borthakur, 1990; Grounds et al., 1995; Taylor, 1998; Juenger et al., 2011) or calcium hydroxide and potassium hydroxide (Kamlet, 1960). Few investigations have studied SSCs composed of natural pozzolans (Cabrera-Luna et al., 2018).
The purpose of this research is to present a study of the mechanical properties and microstructure of concretes manufactured with SSC composed of pumice (PM). At 28 days of age, the concretes were exposed to dry laboratory conditions and immersed in a solution of 3.5% CaSO₄. This study is part of research on volcanic-based SSC (Cabrera-Luna et al., 2018).

2. MATERIALS

Supersulfated cement is based on PM material of volcanic origin, with a surface area of 600 m²/kg, two sulfate sources—commercially available HH and industrial byproduct An—and two alkaline sources—Portland-composite cement PCC 30R (PC) (ONNCCE, 2014) and commercially available calcium oxide (CaO). Table 1 shows the chemical composition of the main oxides of the starting materials.

The fine aggregate was of volcanic origin with a fineness modulus of 2.84. The coarse aggregate had a maximum nominal size of 12.5 mm and a volumetric density of 1,388.54 kg/m³. A polycarboxylate-type superplasticizer was used to maintain the water/cement ratio of 0.30 and slump of 75 to 100 mm.

3. EXPERIMENTAL PROCEDURE

3.1 Design of mixtures and manufacture of specimens

Four concrete mixtures were designed based on the procedure proposed by the absolute volume method, published by ACI 211.1 (ACI Committee 211, 2002), with a water/binder ratio of 0.30, with regard to 720 kg/m³ of a cementitious material and a slump of 75 to 100 mm. Four different cementitious materials were used, composed of 1) 5%HH-20%PC-75%PM, 2) 15%HH-10%PC-10%CaO-65%PM, 3) 5%An-10%PC-10%CaO-75%PM, and 4) 15%An-20%PC-65%PM. Table 2 shows the quantity of cementitious compounds. A reference concrete was made with 100% PC (CR).

For the compressive strength test, cubes 100 mm on each side were manufactured according to UNE-EN 12390-1 (AENOR, 2001). The concrete specimens had an initial curing treatment: one at 25 °C (T25) for 24 h and another at 60 °C for 22 h and then at 25 °C (T60) for the remainder of time.

After 28 days, the specimens were exposed to two environments: one in dry laboratory conditions at 25 °C (L) and another consisting of 7-day cycles immersed in a solution of 3.5% CaSO₄ at 25 °C and then 7 days under laboratory conditions at 25 °C (S).

3.2 Characterization
The concrete compressive strength was determined up to 180 days by applying a load with a speed of 0.4 MPa/s according to the UNE-EN 12390-3 Standard (AENOR, 2003). Fragments of tested cubes were dried for 72 h in methanol and then in a vacuum chamber at 38 °C for 72 h. Later, fragments of dry cubes were mounted in resin, roughened, polished, and carbon-coated. These specimens were analyzed through a scanning electron microscope (Phillips model XL-30ESEM) operated at 20 kV.

4. RESULTS

4.1 Compressive strength
The reported values represent the average of three cubes. The evolution results of the concrete compressive strength for the curing regime of T25, exposed to dry laboratory conditions at 25 °C (L) and immersed in a solution of 3.5% CaSO₄ at 25 °C (S) up to 180 days of age, are shown in Figure 1. At 28 days, it was observed that the C-2 concrete showed the lowest strength of 22 MPa; however, after 180 days, the strength increased, reaching approximately 41 MPa for both exposure conditions, higher than the value of the reference concrete. In contrast, the C-3 concrete reached the highest strength of approximately 44 MPa when exposed to the 3.5% CaSO₄ solution, 24% higher than the reference concrete (C-R) at 180 days of age. The standard deviation values of the averages were ±0.10–2.30 MPa.

Figure 2 shows the compressive strength results of the specimens for the curing regime of T60, exposed to laboratory conditions at 25 °C and immersed in a solution of 3.5% CaSO₄ at 25 °C. The compressive strength of the C-1 and C-3 concrete at 28 days reached values of approximately 32 MPa, similar to C-R; however, after 180 days of exposure to laboratory conditions, C-1 and C-3 reached approximately 42 and 44 MPa, respectively, higher than the reference concrete with 36 MPa, while C-3 immersed in a solution of 3.5% CaSO₄ reached 46 MPa. The initial curing favored the initial and later strength in agreement with previous results (Cabrera-Luna et al., 2018). The standard deviation values of the averages were ±0.17–1.76 MPa.

In general, it was observed that the chemical composition and initial curing influenced the strength development according to previous results (Cabrera-Luna et al., 2018). These factors favorably influenced the densification of the matrix, providing resistance to the calcium sulfate (Grounds et al, 2003). However, the strength development of SSC is slower than that of the PC (Noor-ul-Amin, 2014) because the hydration process of SSC is slow at early ages, and then, the concrete compressive strength abruptly increases at advanced ages (Ding et al., 2014). The increase of compressive strength beyond 28 days may be related to the speed of the hydration products and the morphology of the formed plaster (Cabrera-Luna et al., 2018).
Compressive strength and microstructure of concretes manufactured with supersulfated cement based on materials of volcanic origin exposed to a sulfate environment

K. Cabrera Luna, J. I. Escalante García, D. Nieves Mendoza, E. E. Maldonado Bandala

Figure 1. Compressive strength of specimens for the T25 regime exposed to dry laboratory conditions (L) and immersed in a solution of 3.5% CaSO$_4$ at 25 °C (S).

Figure 2. Compressive strength of specimens for the T60 regime exposed to dry laboratory conditions (L) and immersed in a solution of 3.5% CaSO$_4$ at 25 °C (S).
4.2 X-ray diffraction (XRD)

Figure 3 presents the XRD patterns of the PM and the cementitious compound of 15%An-20%PC-65%PM at 28 days, which was used to make the C-4 concrete. After the chemical activation of the PM at 28 days, the amorphous halo of the PM decreased in intensity and was slightly displaced to the right, suggesting that the PM particles reacted with the activators to form the hydration products, such as ettringite, An, gypsum, and C-S-H, identified as the primary hydrating phases. The An reflection peaks reveal low solubility and reactivity, which influenced a low amount of formed ettringite. This agrees with the presence of weak ettringite reflection peaks, suggesting that late-age strength development is mainly due to the formation of C-S-H according to (Cabrera-Luna et al., 2018).

![XRD patterns of the composite cement 5%An-20%PC-75%PM (C-4)](image)

4.3 Scanning electron microscopy (SEM)

Figure 4 and Figure 5 show the microstructure of the C-3 concrete (5%An-10%PC-10%CaO-75%PM) for the T60 regime exposed to dry laboratory conditions at 25 °C (L) at 28 days and immersed in a 3.5% CaSO₄ solution at 25 °C (S) at 90 days, respectively. The images were obtained using backscattered electrons. In all micrographs, PM particles identified by an irregular morphology of different sizes were observed, suggesting that not all particles reacted to form hydration products; moreover, due to their size, it is easy to distinguish aggregate particles embedded in the matrix of reaction products. An particles were not observed, suggesting that the Ca²⁺ and SO₄²⁻ ions reacted with the alumina phase of the PM to form ettringite (Juenger et al., 2011; Sadique et al., 2012; Bazaldúa-Medellín et al., 2015; Gracioli et al., 2017; Rubert et al., 2018). In Figure 4, the absence of PC grains suggested that they reacted with water to form more Ca(OH)₂, promoting the dissolution of PM to produce C-S-H and other products (Sadique et al., 2012). The microstructure was dense with cracks caused by the drying of the gel under the high vacuum conditions in the electron column of the microscope (Avila-López et al., 2015). In general, the matrix–aggregate interface is continuous; no cracks were observed in this area, showing good adherence. However, in the polished samples, the ettringite was difficult to detect; moreover, it easily decomposed under the high vacuum drying conditions of the electron column of the microscope (Bazaldúa-Medellín et al., 2015). Although the X-ray microanalysis spectra (EDS) allowed their identification, they showed that the primary hydration products of the SSC concretes are...
were C-S-H and ettringite, distributed through the finely intermixed matrix. This agrees with (Cabrera-Luna et al., 2018). The presence of ettringite crystals provides strength instead of expansion (Sadique et al., 2012); these crystals were deposited in the air voids (Wolfe et al., 2001) initially occupied by water (Cabrera-Luna et al., 2018), densifying the matrix microstructure together with the C-S-H (Bazaldúa-Medellín et al., 2015) and improving the strength. Therefore, this phase was not accompanied by expansion (Wolfe et al., 2001), and there was no visible expansion in the concrete samples after 180 days. These results coincide with the XRD patterns.

Figure 4. SEM images with backscattered electrons of the C-3 concrete (5%An-10%PC-10%CaO-75%PM) for the T60 regime exposed to dry conditions at 25 °C for 28 days.
Compressive strength and microstructure of concretes manufactured with supersulfated cement based on materials of volcanic origin exposed to a sulfate environment

K. Cabrera Luna, J. I. Escalante García, D. Nieves Mendoza, E. E. Maldonado Bandala

5. DISCUSSION

Concrete degradation by sulfate attack mechanisms depends on several factors, such as cement type, presence of mineral additions, water/cement ratio, cation type associated with sulfate anions, sulfate concentration, time and duration of exposure, environment, hydration degree, and curing conditions (Hossain and Lachemi, 2006; Prasad et al., 2006; Indu Siva Ranjani and Ramamurthy, 2012), in addition to other parameters, such as pore structure, permeability, diffusivity and mechanical properties (Prasad et al., 2006). In concretes made with PC, the degree of sulfate attack depends on the availability of Ca(OH)$_2$ and C$_3$A (Hossain and Lachemi, 2006); therefore, the chemical composition of the cement has an important role in its resistance to sulfate (Prasad et al., 2006). The SSCs of this investigation were based on volcanic PM, calcium sulfate and alkaline sources. When the SSCs were exposed to a calcium sulfate solution by means of hydrating and

Compressive strength and microstructure of concretes manufactured with supersulfated cement based on materials of volcanic origin exposed to a sulfate environment
drying cycles, they increased in stability and strength, with stable microstructures. This suggests that the external sulfate ions did not have suitable conditions to decalcify the Ca(OH)₂ or C-S-H. Moreover, the decrease in PC consumption reduced the amount of calcium aluminates, which had already found an abundant source calcium sulphate from the additives of the SSC, so these formed ettringite that stabilized as such; moreover, the low Al content from the PM and abundance of calcium sulphate also minimized the possibility of deleterious delayed ettringite. Nonetheless, the expansion does not only depend on the amount and time of formation of ettringite; the location of formation is also important (Wojciech, Marczewska and Jaworska, 1985); in this case, the nature of the microstructures, the rate of reaction of the components of the SSC, favored a sequence of reactions and deposition of reaction products that showed in a favorable balance that resulted in strong microstructures forming durable cements. On the other hand, the low water/binder ratio used must have had a positive effect, as it reduced the volume and connectivity of the porous network, which reduced the penetration of external agents (Indu Siva Ranjani and Ramamurthy, 2012). In general, no physical degradation was noted during the period of study, such as cracking, spalling, loss of strength and adhesion. The concretes SSC seem suitable for use in marine conditions and for construction of sewage pipes.

6. CONCLUSIONS

The compressive strength of specimens cured at 25 °C showed that the concretes made with cementitious compounds of 15%HH-10%PC-10%CaO-65%PM and 5%An-10%PC-10%CaO-75%PM reached approximately 41 and 44 MPa, respectively, when immersed in a solution of 3.5% CaSO₄. Supersulfated concretes with cementitious compounds of 5%HH-20%PC -75%PM, 5%An-10%PC-10%CaO-75%PM and 15%An-20%PC -65%PM cured at 60 °C showed greater strength than the reference concrete by up to 30% when immersed in a solution of 3.5% CaSO₄. The main hydration products of the supersulfated concretes detected by XRD, SEM and EDS were C-S-H and ettringite, which provided a favorable compressive strength when exposed to laboratory conditions and calcium sulfate. Curing at 60 °C for 22 h favors early-age strength and late-age development, mainly in the samples exposed to sulfate in almost all concretes. The microstructure of the concrete with a cementitious compound of 5%An-10%PC-10%CaO-75%PM showed unreacted PM particles and aggregates embedded in a paste structure of a relatively dense matrix. In general, supersulfated concretes show favorable compressive strength values when exposed to a 3.5% CaSO₄ solution, presenting adequate properties for use in marine environments.

7. ACKNOWLEDGEMENTS

The authors would like to thank the National Council of Science and Technology for the scholarship to K Luna-Cabrera and the Conacyt FC-2015-2 / 906 project for financial support.
